The date shows when this volume was taken.

RR FEB 5 '77

All books not in use for instruction or research are limited to all borrowers.

Volumes of periodicals and of pamphlets comprise so many subjects, that they are held in the library as much as possible. For special purposes they are given out for a limited time.

Graduates and seniors are allowed five volumes for two weeks. Other students may have two vols. from the circulating library for two weeks.

Books not needed during recess periods should be returned to the library, or arrangements made for their return during borrower's absence, if wanted.

Books needed by more than one person are held on the reserve list.

Books of special value and gift books, when the giver wishes it, are not allowed to circulate.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

EDITED BY

GEORGE F. SHRADY, M.D.

Volume 2.

Original Communications.

THE MEDICAL USE OF ELECTRICITY.

BY G. M. BEARD, M.D., AND A. D. ROCKWELL, M.D., OF NEW YORK.

No. II.

IT was once remarked by a distinguished philosopher that "we may be sure that a science is in its infancy when its advocates are particularly dogmatic in the expression of their beliefs."

Judged by this standard, the science of the medical use of electricity is just emerging from infancy into childhood, for its disciples are far less positive in the declaration of their views in regard to the unsettled points connected with it, than were the original investigators fifteen years ago. A brief survey of the history of recent explorations in this department will fully explain our meaning. In 1850, Duchenne, of Boulogne, published a work entitled, "Exposition d'une Nouvelle Methode de Galvanization, dite Galvanization Localisé," in which he announced the leading idea of his system, namely, that "one can localize the electric stream over a fixed point under the skin, if the end of a conductor be covered with a moist sponge, and strongly pressed upon the skin." In 1855, he published another work, an epitome of five years of experience, entitled, "De l'Electrization Localisé et de son Application à la Physiologie, à la Pathologie, et à la Therapeutique." This book excited not a little attention, and really created an era in medical science. It aroused the enthusiasm of the author's countrymen, who had the opportunity of witnessing his brilliant demonstrations, and was abridged for the German physicians, by Dr. Erdmann. But the number of those who were inspired to enter the list as investigators was comparatively small. Like all the original explorers in this department, Duchenne laid special stress on his physiological experiments. At no era of medical science had there been found any considerable number in any country who were willing and able to devote their lives to purely experimental researches that achieve no direct practical results. While Duchenne had astonished both himself and the scientific world by the novelty of his experience, neither he nor his admirers were fully alive to the immense therapeutical value of his discoveries. As a consequence, the cause of electro-therapeutics would not be espoused by those who felt compelled to turn all their endeavors to practical account, and but very few of those who warmed into enthusiasm over his demonstrations were willing to occupy themselves exclusively in the same field. But Meyer of Berlin, Baierlacher of Nürnberg, Althaus of London, made a specialty of this department, and have published works in which the method of Duchenne is adopted as the basis. Remak, of Berlin, was one of the few who were sufficiently alive to the value of Duchenne's experiments to pursue the subject still further, and in 1855 he embodied his experience in a work entitled "*Ueber Methodische Electrisirung Gelähmter Muskeln*,"—"On the Methodical Electrization of Paralysed Muscles"—in which he announced a system entirely different from that of Duchenne, and became the leader of an opposite school. The leading idea of his work was this: "That in order to bring a muscle to complete contraction, it is far better to excite its motor nerves than to allow the stream to operate upon the muscular substance itself."

Moreover, he employed the galvanic stream almost entirely, while Duchenne had performed his experiments with the faradaic current. Remak reported astounding cures, but at first failed in enlisting the sympathy of the profession. Subsequently, however, he learned wisdom by experience, and became more wary in his statements, and calmer in his manner of expression. Gradually the profession accorded to him their confidence, and some of the ablest minds of Germany—among whom we may name Benedict, Schulz, Meyer, Neumann, Rosenthal, Frommhold, and Eulenberg—are numbered among his disciples. For some time a fierce and unreasonable controversy was carried on between Remak and Duchenne, which, both in its character and in its results, singularly reminds one of the fabled story of the knights who quarrelled over the pictures on the opposite side of the public sign. Remak contended for the application of the galvanic stream on the motor nerves, while Duchenne persisted that the best results were obtained with the faradaic, or induced current, on the muscles themselves.

At a public trial in Paris (as we are informed by Garratt), Remak demonstrated on a living subject that so far as producing contraction of a muscle goes, the induced current applied to the motor nerves is far less painful than when applied to the muscular substance. But so far as the general remedial effects of electricity are concerned, both were in the right, as is now tolerably well established.

So far as is yet ascertained, the remedial effects of electricity, whether employed in the form of galvanization or faradaization, are governed by no fixed laws. Experience is our only guide in their use. All the investigations of scientific men have thus far failed in reducing to any system the different therapeutical effects of the galvanic and the faradaic or induced currents.

Although there has been not a little speculation on this very theme, and although numberless experiments have been instituted with a view to establishing the superiority of the one or the other, yet we believe that the most progressive and candid of the investigators of the present day are willing to admit that the whole subject is yet in chaos. It has been found that the brilliant results that Remak obtained by the galvanic stream can also be secured by the use of the secondary current, and it has also been found that they are, so far as we can judge, very capricious in their effects, setting at defiance all the attempts of inquiring minds to reduce their employment to a logical system.

Those who are accustomed to use the various kinds of electricity, namely, the galvanic or constant stream from a large number of elements, and the primary and

secondary induced current of the electro-magnetic machine, testify that while all are beneficial, *no one* has been found to be so superior to the others as to justify its exclusive use. It has been thought that the galvanic stream was more serviceable in rheumatic and neuralgic affections, and in paralysis dependent on central nerve derangements; but this is very far from being established.

There are cases where at first the induced current acts more speedily than the galvanic stream, which cases, later on, seem to be more amenable to the latter. One day a patient may present himself with a rheumatic disorder that is at once relieved by faradaization, and the next day another patient with precisely the same disease, at precisely the same stage, is more speedily aided by galvanization.

More than that, there are cases which at the beginning of the *séance* are benefited by galvanization, and before its close yield to faradaization. Nay, further, there are instances where one form of electricity seems to irritate for the time being, while the other at once calms and soothes. What, then, is the law of their operation? There is none, so far as can be determined in the present state of our pathological knowledge, and there is no guide to their use except experience. The German investigators have carefully studied the effects of the different forms of electricity in exciting muscular contractions, and they have refined this subject, as it appears to us, to an absurd and profitless excess. Ziemssen has experimented largely on the dead subject, and has ascertained the particular border points that are most susceptible to the electrical influence.

It has been very clearly established that muscular contraction is produced more completely and with less pain when the electrodes are placed on the "border points" where the motor nerve enters the muscle, than when applied to the bellies of the muscles themselves.

With these views of Remak and Ziemssen our experience fully accords. We have found that in certain cases of atrophy and loss of power, where we fail in producing contractions by application directly over the muscles, we do succeed very unaccountably by pressing the fingers along and underneath the borders of the same muscles.

We have found that some inveterate cases of rheumatism that evinced no signs of yielding when the hand was applied in a general way, at once took a favorable turn when the fingers were pressed along and underneath the borders of the muscles concerned.

But important as is this fact, it is hardly worthy of the attention it has received at the hands of some of the German investigators.

Ziemssen and Rosenthal seem to act on the supposition that electricity is chiefly useful in cases of paralysis, whereas its proudest victories have been gained over long-standing dyspepsia, constipation, neuralgia, amenorrhœa, chorea, hysteria, and other disorders connected with enfeebled vital organs, and a deranged nervous system.

On the other hand, we have found that the different forms of paralysis that present themselves to us for treatment give far less speedy and satisfactory results to the electrical treatment than almost any other form of disease. And yet physicians and the laity are possessed with the idea that paralysis is, *par excellence*, the disease that justifies the use of the battery.—Our present knowledge of the therapeutical value of the different forms of electricity may be thus summed up:

1st. Galvanization and faradaization are of so nearly equal value in paralytic, rheumatic, and neuralgic affections, that we are hardly justified in employing one to the exclusion of the other. It would seem that the best results are obtained when they are used with alternations and variations, according to the indication of their effects.

2d. Muscular contractions are excited with the least pain and most speedily when the electrode (either a sponge, a metal, or the hand) is applied along the edge of the muscle, and especially at the border point where the motor nerve enters the muscular substance.

3d. The ascending faradaic current has a great power of exciting muscular contractions, and stimulating the nerves, and is especially indicated in local paralysis, anchylosis, and plastic effusions. Applied through the body with the positive pole at the feet, its effects are not unfrequently very disagreeable.

4th. The *descending faradaic current, thoroughly applied, with the negative pole at the feet, is a tonic and corrective of far greater efficacy than any other remedy or combination of remedies now known to science.* Judiciously given, it can never work harm, save in cases of pulmonary tuberculosis, and in such cases we rarely employ it.

5th. The hand is by far the best electrode, and for the following reasons:

(*a*) It is more effective, from its wondrous power of adaptation. The fingers, better than sponge or metallic electrode, can feel their way along the border of the muscles and press towards the deeper tissues.

(*b*) By no other instrument can the patient receive the same quantity of electricity with so little irritation, particularly when applied on the head, or over any sensitive diseased organ.

6th. *Although paralysis in its different forms is usually more benefited by electricity than by any system of internal medication, it is yet among the least tractable of the various diseases that present themselves for this method of treatment.*

7th. *The diseases which are found to yield most readily and surely to the different forms of electricity in the various modes of application, are neuralgia, dyspepsia, rheumatism of the subacute and chronic varieties, chronic bronchitis, constipation, amenorrhœa, anœmia, hysteria, and general debility.*

8th. The electric streams are of great value as adjuvants in the diagnosis of disease, inasmuch as any deviation from its normal sensitiveness of any part to their influence is readily indicated. In this way we learn where the disease is located, although we may not be able to determine its precise nature.—In order to illustrate more clearly to the profession the method and result of our treatment by faradaization, we propose to give in detail some of the more interesting cases of the various forms of disease in which we have employed it. We can hardly expect that the bare statement of the curative powers of electricity will receive absolute credence without the presentation of some typical examples.

Even Remak himself (as stated above) at first experienced not a little difficulty in gaining the confidence of scientific men. So easy is it to represent on paper what is very difficult to practically achieve, and so ready are specialists to dignify their own peculiar method of treatment to the exclusion of all others, that we cannot hope for the full appreciation of the wondrous powers of electricity, except by those in the profession who may be led to employ the descending faradaic current as faithfully and persistently as we have ourselves.

Neuralgia.—This horrible affection, which so often disheartens both physician and patient, we have found to yield to the persistent application of electricity, as uniformly perhaps as any other disease, unless it may be nervous dyspepsia. Whether it exists either in the weakly or the strong it is always greatly alleviated and

generally cured, sometimes by a few applications, in other cases by a protracted treatment.

Indeed our unexpected success in certain cases did much to stimulate us to make special investigation on the whole subject of electricity.

Case First.—In the latter part of August of last year, Mr. B——, a broker down town, came to our office complaining of a severe neuralgia of the back of the head and neck, that had rendered his life miserable for one year and a half. He had consulted many physicians and had taken much medicine, but had found little relief. He was a tall, well formed, muscular man, with a hard, full face, that suggested great native vigor of constitution.

With not very strong assurance of hope, either on our part or on his, the treatment by the descending faradaic current was recommended and commenced on the 5th of September. He was relieved on the first application, which was a very thorough one, and extended over all the vital organs. On the 8th of September he again came for treatment, and reported himself as much improved. On the 10th he reported himself as being entirely free from pain. Another application was then made, and he bade us good-by, preparatory to going into the country. We could hardly believe that the cure could be anything more than temporary, and were not surprised when he again presented himself on his return and informed us that his old enemy had made him another gentle visit.

We gave him another thorough application. A short time since he called at our office, and informed us that up to that time he had been perfectly well.

Case Second.—Miss H. The following case proves that that most distressing and persisting of all neuralgic troubles, tic douloureux, may be cured where medication has failed.

This patient presented herself for treatment in the early part of September, expressing herself, however, as having but little hope of experiencing more than a slight temporary relief.

Previously she had been treated by electricity with some short-lived benefit; sufficient, however, at that time to inspire her with hope. She was doomed to disappointment, for in a very few weeks the paroxysms of intense pain, which before had made her life miserable, returned with greater severity than ever. As she told her story, the sudden, sharp, shooting pains in her face would every few minutes cause her in agony to hold her speech. To such an extent had this mysterious disease affected her that occasionally her tongue seemed almost paralysed, and at times her utterance was thick and broken. These frequent and terrible paroxysms had left imprinted on her pale face an expression of constant care and suffering. Her own estimate of the value of life was that death was preferable to an existence of such constant agony. Her physician had tried almost everything in the materia medica supposed to be beneficial in such cases; and so without delay, doubting yet hoping, we commenced treatment by faradaization. The patient came every other day, and for the first two or three times only a comparatively mild current was given.

The strength was gradually increased, but no improvement was manifest. After the seventh or eighth application, however, a current, as strong as the operator and patient could well bear, was given for fifteen or twenty minutes, at each sitting, and in addition to the external application, the tongue was thoroughly electrified by means of a metallic spatula. From this time a rapid improvement was noticed.

The paroxysms occurred less frequently and with less severity. She discontinued treatment on the 20th of October, having had no return of pain for three weeks. Up to this date, January 2, she has had, so far as we can learn, no return of her trouble. Whether in this particular case the cure is *absolutely* permanent it is of course impossible to say; but enough is known to convince the patient and those who knew her that the benefit derived was great and incalculable.

Tic Douloureux, as is well known by any who may have had much experience in the application of electricity for the disease, is the most difficult to cure or benefit of all neuralgic affections.

Of the neuralgias, the cervico-occipital, intercostal, lumbo-abdominal, and cephalalgia, are all in the vast majority of cases speedily cured; and although some cases of facial neuralgias, which have resisted all treatment by medication, still fail to be benefited by electricity, yet it is our experience that the great majority even of such cases are permanently cured by persistent treatment.

Case Third.—The power of electricity over neuralgia of a specific character was very well illustrated in the case of a Mrs. B., sent to us by Dr. Cummings.

When she first consulted us she represented that for years she had been suffering from a terrible neuralgia in the head, and which at times attacked other parts of the body. For six weeks the pain had been so severe that she had been unable to pursue her usual avocation, which was that of an operator on a sewing machine. She was a plump, fleshy individual, with full round cheeks, indicative of anything but delicate health. Indeed so vigorous did she seem that we told her that only local applications would be necessary in her case, and accordingly directed her to place her hands on the sheet of copper to which the negative pole was attached, while a very gentle current was passed over the front and back part of the head. The application had not been continued more than two or three minutes, when she exclaimed, "Doctor! my pain is all gone; this is the first quiet moment I have had for a long time."

The sitting lasted about ten minutes, and at its close she was directed to come again on the following day. The next morning she informed us that she had experienced no more pain in her head, but that "the disease had gone to her breast and shoulders." This fact, taken in connexion with some other statements that she had incidentally made the day before, led us to suspect that syphilis was the cause of her sufferings. In reply to questions, she confessed to every symptom of secondary syphilis, and in fact had been aware all along that the disease was in her system. According to our habit in such cases, we made the applications down the spine and over the vital organs. The relief was complete, although not as instantaneous as the day previous. Several times the applications were renewed at intervals of two or three days, and each time she expressed herself as very enthusiastic over the improvement she was making. We examined her throat with the laryngoscope, and found a slight degree of inflammation, which readily yielded to the nitrate of silver. The fifth time she came she reported that she had returned to her work, and was able to labor nearly as hard as at any time in her life. The horrible nocturnal pains had entirely disappeared, and her sleep, which before had been so much interrupted, was quiet and refreshing. There remained, however, some neuralgic distresses in the eyes, which disappeared after a few more local applications.

LARYNGOSCOPY.

By J. SOLIS COHEN, M.D.

OF PHILADELPHIA.

No. VI.

DEMONSTRO-LARYNGOSCOPY.—THE EXHIBITION OF A PATIENT'S LARYNX TO OTHERS.

(Continued from page 540, Vol. 1.)

When the epiglottis is well raised we gain a view of the whole circumference of the superior laryngeal aperture. This is triangular, somewhat cordiform, wider in front than behind, sloping down obliquely backwards, and terminating behind in the vertical inter-arytenoidal fissure. Its border is formed in front by the free rim of the epiglottis; then on either side by the ary-epiglottic fold, which arches backwards in the form of a bow until it reaches its arytenoidal attachment posteriorly, where it surrounds a rounded eminence, the cartilage of Santorini; and the two arytenoids, with their connecting muscle and mucous fold, complete the border behind. An enlargement on each side in front of the cartilages of Santorini, and breaking the arch of the ary-epiglottic fold into two unequal festoons, is produced by the inclosed extremity of the staff-like cartilage of Wrisberg surrounded with glands and adipose tissue.

A reflection of mucous membrane runs from one arytenoid cartilage to the other, which, during ordinary respiration, can be distinctly seen forming the posterior boundary of this superior portion of the larynx; but during vocalization the contraction of the arytenoid muscle approximates the cartilages, and the band of mucous membrane folds up, exposing the vertical fissure. The obliquity of this border renders the thyroidal wall of the larynx much deeper than the arytenoidal. Dr. Elsberg, of New York, writes, that in this posterior wall he has detected the presence of tubercles long before the ordinary physical signs of phthisis could be recognised, and that after results verified this early prognosis. Czermak, Stork, Lewin, and others, have recorded similar observations.

If we look down along the inner or laryngeal face of the quadrangular membrane, we will see on either side, about half an inch below its superior border, the red mucous membrane folding under on itself, forming the *false vocal cord*, a broad mucous fold, and leaving between it and the horizontal surface of the true vocal cord, seen immediately below as a white, glistening band extending from before backwards, an oblong interval, which is the ventricle of the larynx, and which leads up into the laryngeal sac. By means of a deep inspiration, especially if short, sudden, and following vocalization, these ventricles can be rendered more distinct, and a separation of their walls be observed dilating the cavity. The size of the ventricles, or rather the space constituting them, varies. It is contended by some anatomists, that these false vocal cords are not merely duplicatures of mucous, or of mucous and elastic membrane, but that they are composed in part of ligamentous tissue (superior thyro-arytenoid ligament) and some muscular fibre. It is generally conceded that they contain a delicate narrow band of fibrous tissue continuous with the fibrous capsule of the laryngeal sac, but destitute of muscular fibre. In the mucous membrane of this sac there open, as first described by Hilton, some sixty or seventy small follicular glands, situated in the submucous areolar tissue. Its laryngeal surface is covered by the inferior portion of the aryteno-epiglottideus muscle (compressor sacculi laryngis of Hilbon) which compresses the sac and discharges its secretions upon the true vocal cords, which, being themselves unprovided with glands, are thus lubricated.

The floor of the ventricle is formed by the *true vocal cord*, which is easily recognised by its semi-metallic lustre—a mother-of-pearly white in the female, with a yellowish dash in the male; a strong, thick, fibrous band (the inferior thyro-arytenoid). The sharp edge of this band constitutes the vocal cord par excellence. This structure, at least its lower surface, is an extension inwards of the vocal membrane, or the middle crico-thyroid ligament. Each cord consists of a compact band of parallel fibres of elastic and fibrous tissue, arranged in prismatic form, the base being outwards, so that a vertical section shows the upper surface horizontal, and the lower surface taking an oblique direction downwards and outwards ≺. Firmly imbedded into the external portion of the vocal cords are some short pennated fibres from the vocal muscle, the thyro-arytenoid, which is adherent and parallel to it, attached in front to the receding angle of the thyroid, and behind to the arytenoid. When the two true vocal cords are approximated, their horizontal surface forms a floor to the upper laryngeal cavity. They form with the space between their free edges *the glottis;* their sharp borders are *the lips of the glottis*, and the chink or fissure between these lips is the *rima glottidis*. These terms should not be confounded. The length of the rima in the male varies from ten to thirteen lines; in the female, from seven to ten lines; in children it is much less, and when dilated the space across will vary ordinarily from three to six lines, but when widely dilated by a deep inspiration, it may be from six to ten lines, leaving a space large enough often to admit a good sized finger. The rima of the glottis is not formed by the vocal cords alone, but also by the inner face of the arytenoids posterior to the points of attachment of the cords; so that we speak of an inter-ligamentous rima corresponding to the length of the cords, say eight lines, and an inter-cartilaginous rima posteriorly, about three lines. Luschka is disposed to decry this division, which is due in appearance to the knuckling inwards of the posterior attachments of the cords when the posterior vocal processes converge inwards.

The form of the rima glottidis varies.—During ordinary respiration it is a narrow interval somewhat enlarged and rounded behind, looking not unlike the lozenge-shaped space formed by pressing together the tips of the two thumbs and the tips of the two fore-fingers, and then extending the thumbs rather strongly posteriorly and the fingers anteriorly, when the space separating the two thumbs will represent the inter-cartilaginous rima, and the remaining space the inter-ligamentous rima. When widely dilated, the rima acquires the form of an equilateral triangle, the base being behind. The form of the rima varies greatly during phonation, and may become elliptical, oval, or circular, as the cords are acted upon by the complex thyro-arytenoid muscle, with portions of which their structure is blended, and by the contraction of other muscles attached to the arytenoids.

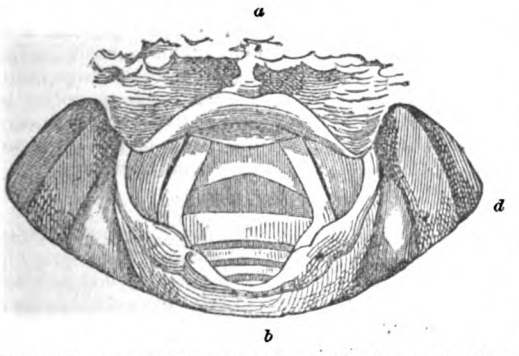
When the epiglottis is well raised from the laryngeal aperture, as by the emission of a high musical note, so that the anterior portions of the vocal cords can be discerned, we often see below the small end of the pad of the epiglottis, immediately beneath the junction of that cartilage to the thyroid, and separating the anterior attachments of the false vocal cords, a well marked, sharply-defined, pinhead-like pit or foramen in the mucous membrane. This is the *fovea centralis* of Merkel, and communicates directly on both sides with the anterior entrance into each laryngeal sac, being continuous below with a shallow groove formed by a short fold of the

laryngeal mucous membrane which stretches across from the anterior end of one vocal cord to the other. This fovea centralis is one of the chief points of insertion for the elastic membrane. Though very small in the human subject, it is said to be quite large in many lower animals, as in the horse, where it seems to constitute a middle ventricle to the larynx.

The anterior and posterior points of insertion of the vocal cords are seen upon them as four yellowish freckles, the *maculæ flavæ*, which mark the positions of the vocal processes.

The mucous membrane, as it passes from one arytenoid cartilage to the other, is thrown into loose folds known as the *commissure* of the arytenoids, and is best seen stretching across when the arytenoids are separated. As these cartilages approach each other, this commissure becomes folded up, as it were, within the vertical cleft or notch, the *arytenoid fissure*, often termed improperly the posterior glottis.

The accompanying figure, borrowed from the monograph of Semeleder, presents such an appearance as would be obtained during deep inspiration with the epiglottis moderately raised, could all the parts figured be seen in a single view.



The parts seen in the mirror from *a* to *b* are, the base of the tongue with its circumvallate papillæ, the indented crest of the epiglottis, a portion of its upper laryngeal face, and part of its belly protruding beneath and cutting off the view of the anterior extremities of the vocal cords; then through the widely opened glottis and beneath the vocal cords, the inferior portion of the interior face of the angle of the thyroid; beneath this, the middle crico-thyroid ligament; then the broad cricoid cartilage, and immediately below it, two or three rings of the trachea; below this we see the posterior border of the laryngeal aperture, formed by the commissural fold stretched between the two separated arytenoids; below this, the posterior external wall of the larynx down to the transverse groove which marks the commencement of the œsophagus.

In the horizontal direction from *c* to *d*, commencing with the lateral boundary of the rima glottidis on either side, we see the true vocal cord disappearing beneath the belly of the epiglottis, which conceals from view its anterior attachment and proximity to its fellow; then directly upon it the entrance into the ventricle of Morgagni represented by a thick, dark line; above, and to the outer side of this, the broad fold of lining membrane constituting the false vocal cord; outside of this, and above it, the ary-epiglottic fold arching inwards and downwards towards the commissure behind to meet its fellow, where is seen a swelling directed towards the interior and formed by the cartilage of Santorini; and further outwards and forwards, a second swelling in the fold, formed by the extremity of the cartilage of Wrisberg. Below this fold, and outside, we see a portion of the exterior wall of the quadrangular membrane; and outside of this, the triangular pyramidal sinus leading down to the entrance into the œsophagus, and bounded on its outside by the wing of the thyroid cartilage. The bright spot depicted in this space corresponds to a point on the inner surface of the thyroid plate, shining through its thin mucous membrane, and the enlargement above this is formed by the greater horn of the hyoid bone.

Under unfavorable circumstances, the view is limited to a portion of the base of the tongue, the edge of the epiglottis, more or less of the arytenoid cartilages, and some portions of the posterior wall of the pharynx.

If we wish to examine the whole laryngeal face of the epiglottis and the anterior extremities of the vocal cords, we direct the patient to sound a high note quickly and with a little force, which effort raises the larynx, closes the glottis, and throws the epiglottis up with a jerk, so that the horizontal surface of the vocal cords is distinctly seen, as well as the false vocal cords and the ventricles. An inspiration accompanied by sound, or an ironical laugh, will bring the same structures in view. If this does not suffice, some of the instruments described (page 349, first volume) for pulling the epiglottis forward may be employed. When a depressed epiglottis prevents a view of the cords, we may judge of their flexibility by the movements of the arytenoids, which can almost always be recognised.

To examine the posterior extremities of the vocal cords, the anterior surfaces of the arytenoids, the arytenoid commissure, and the inner posterior wall beneath, we reflect the light more posteriorly by inclining the mirror towards the horizon during an inspiration, which opens the glottis and separates the arytenoids, which look upwards, backwards, and outwards, exposing their anterior faces.

To examine the posterior walls of the arytenoids down to the cricoid, and obtain a good view into the pyramidal sinuses, we direct the emission of sound, so as to close the glottis; in doing which, the arytenoids approach, exposing their pharyngeal surface, separating more widely the quadrangular membranes from the plates of the thyroid.

To obtain a view further down the trachea than is represented in the figure, we place the mirror more perpendicularly, and direct a deep inspiration, so as to open the glottis to its fullest extent, and then, by a little manipulation, reflecting the light more anteriorly, we may see several tracheal rings as narrow bands, colored like the conjunctival membrane of the eyelid, arching across with their concavities downwards, becoming narrower and closer as they are more distant, until the foreshortening is such that they cannot be distinctly counted; and sometimes in this way, when the circumstances are favorable, such as a good mirror, a steady hand, a well directed light, a straight tracheal axis, a wide glottis, &c., we can gain a view clear down to the bifurcation of the tube. Sometimes, when we fail to obtain such an extended view with the light, patient, eye, and mirror in the ordinary position, we can succeed by elevating the position of the patient so that the eye of the observer shall be below the plane of the patient's mouth; then throwing the light from below upon the laryngeal mirror, which is to be held horizontally, the light can be reflected clear down the windpipe, and we can see most distinctly the increasing foreshortening of the tracheal rings; and if the bifurcation be visible, we see behind the last ring (below in the mirror), instead of the complete arch with its concavity downwards, a bright triangular space, base up, and on either side of this triangular space, which often seems to project up into the interior of the tube, dark, circular discs marking the commencement of the bronchiæ. If the right bronchus

is very straight, sufficient light can sometimes be thrown in to demonstrate more or less of its extent.

A good rule by which to hunt for the view of the bifurcation is, to get a good view of the laryngeal face of the epiglottis, and then, with this as a guide, to continue inspection along this plane right down the anterior surface of the trachea, gradually lessening the obliquity of the mirror as we gain a deeper view.

If, when a view of the trachea has been obtained, we turn the mirror a little to one side, we obtain a lateral view of that tube resembling the turns of the thread in the nut of a screw.

THE MUSCULAR FORCES PRODUCING CHANGES IN THE FORM OF THE GLOTTIS.

Before leaving the demonstrative portion of our subject, it will be necessary to allude to the muscles moving the laryngeal structures, and to whose contractions are due the various alterations of form observed during the performance of the physiological functions of respiration and vocalization.

In the first place, there are several muscles outside of the laryngeal tube.

1. *Crico-arytenoideus posticus*, one on each side, occupies the lateral half of the posterior face of the cricoid, and runs upwards and outwards to be inserted into the exterior posterior part of the arytenoid surmounting the cricoid on that side. *Use*, to rotate the arytenoid outwards and backwards, and open the chink of the glottis. This muscle may be viewed as the extensor muscle of the respiratory glottis, opening the intercartilaginous rima, antagonizing the arytenoideus.

2. *Crico-arytenoideus lateralis*, one on each side, runs from along the superior margin of the sides of the cricoid, obliquely upwards and backwards to the outer angle of the base of the arytenoid, just in front of the insertion of the posterior crico-arytenoid. *Use*, to draw the arytenoid forwards and outwards, turning the posterior vocal processes inwards, and thus contracting the chink of the glottis in vocalization.

3. *Crico-thyroideus*, one on each side; a triangular muscle running from the anterior lateral surface of the cricoid upwards and backwards to the inferior edge of the thyroid plate, and into its inferior horn, leaving an interval between itself and fellow occupied by that portion of the vocal membrane called middle crico-thyroid ligament. *Use*, to draw the thyroid upon the cricoid with a forward rotary motion, thus stretching the vocal cords, rendering them tense and contracting the chink of the glottis.

Then we have behind, the *arytenoideus*, a single muscle, sometimes described as three distinct muscles. A transverse portion, the deepest, goes posteriorly from the whole length of one arytenoid to the other, covering them completely, except at the very tip; over this portion, two oblique portions cross each other, running respectively from the base of one arytenoid to the apex of the other. Sometimes portions of this muscle are continuous with the thyro-arytenoid and the aryteno-epiglottideus, one or both, seeming to act in consonance with them in closing the larynx. In fact, there seems to be a guttural communication right over this muscle with the posterior portion of the ary-epiglottic fold, leading from the ventricle of Morgagni up the inner posterior wall of the larnyx and out into the pharnyx behind. This gutter or drain is the *filtrum ventriculi* of Merkel, and seems intended to lead off into the pharynx any accumulating secretion from the laryngeal pouch.

The *use of the arytenoideus* is to bring the two arytenoid cartilages in close apposition, which it does very completely by means of its transverse and oblique fibres, so that the plane surface of the posterior vocal processes touch each other and thus close the posterior portion of the glottis. This muscle may be viewed as the flexor of the respiratory glottis. So much for the exterior muscles of the larnyx:

In the interior of the larynx we find several muscular structures inclosed within the quadrangular membrane. These are on each side.

1. *Thyro-epiglottideus*, a delicate muscle running from the posterior inner face of the thyroid near its rentrant angle, just outside of the thyro arytenoid, into the side of the epiglottis. *Use.*—To pull the epiglottis down. This it can do ordinarily only when the tongue is relaxed, and, therefore, the dropping of the epiglottis is usually attributed to backward pressure from the base of the tongue relaxing the middle glotto-epiglottic ligament; but it has been shown by the laryngoscope that some persons can acquire such control over their organs as to drop the epiglottis with the tongue extended; and this would seem to confirm the ascribed use of this muscle as a true depressor.

2. *Aryteno-epiglottideus*, a still more delicate muscle, running from the superior lateral portion of the arytenoid into the side of the epiglottis, some of its fibres being lost in the ary-epiglottic fold. This muscle is indistinctly defined horizontally into what is sometimes described as a superior and an inferior muscle, the inferior portion of which (compressor sacculi laryngis, *Hilton*) compresses the laryngeal pouch and squeezes its secretion out upon the vocal cords. The superior portion will constringe the upper portion of the quadrangular membrane, and, with the thyro-epiglottic muscle, assists to close the superior laryngeal aperture.

THE VOCAL MUSCLE.

There is still another intrinsic laryngeal muscle on each side meriting a more detailed mention than that of its mere origin and insertion. This is the *thyro-arytenoideus*, lying external to the vocal cord and inseparably attached to it, from which circumstance, many anatomists have considered the vocal cord but the tendon of this muscle. It is most usually described as parallel to the outer side of the cord, arising from the lower half of the rentrant angle of the thyroid cartilage and from the middle crico-thyroid ligament, and passing backwards and outwards to be inserted into the anterior and outer face of the arytenoid and into its base; its use being to relax the vocal cords and shorten them, thus lessening the length of the chink of the glottis.

The thyro-arytenoid muscle, however, is quite complex in the arrangement of its fibres, and seems to be the vocal muscle par excellence, to whose contractions are mainly due the various changes of forms produced in the glottis during vocalization, cantation, etc. It has been most thoroughly described by Bataille, who has dissected it minutely, as consisting of three distinct portions, for which reason he has proposed for it the name *triceps-laryngea.*

These three portions are called by Bataille, 1, *faisceau plan;* 2, *faisceau médian ou arciform; and* 3, *faisceau paraboloid.*

The three heads arise in close propinquity from the rentrant angle of the thyroid. *The first or plain bundle* runs back with long, flat, horizontal fibres, to be inserted into the inferior border of the arytenoid cartilage. *The second or middle portion* forms a triangular pyramid, separable into two flat triangles, the base being inserted into the concave face of the arytenoid cartilage, its internal surface being adherent nearly throughout to the 1st or flat bundle; and near its arytenoidal attachment it anastomoses again with this flat bundle by short pennate fibres. Its superior surface is concave, and forms the floor of the ventricle. *The third bundle* assumes the

form of an irregular parabola, with fibres divisible into superior, middle, and inferior layers, and sends out fibres of attachment to the 1st and 2d bundles, and also to the internal wall of the ventricle. The upper edge of the 1st bundle is intimately incorporated into the tissue of the vocal cords by short pennated fibres, and forms a large portion of the constituent structure of the cord, especially of its inferior surface.

The above resumé is but an outline of the minute anatomy of this complex muscle, which makes still further attachments to the epiglottis and other adjacent parts; but it is sufficiently descriptive to show its intricate arrangement and intimate relations with the vocal cord, so that it does not seem irrational to infer that it has no slight participation in producing the various changes of form and tension in the glottis, by means of which a narrow band of tissue, scarce eight lines in length, and barely more than a line in breadth, and with but a single margin free to vibrate, is rendered adequate in response to emotion, or mental conception, to execute the immense variety of sound and modulation of which the human voice is capable. There is but little doubt that the careful study of the mechanical construction of this muscle, coupled with a sufficient number of accurate laryngoscopal observations as to the changes of form in the glottis, and consonant action of other parts attendant upon the production of musical tones in the various registers, will in time disclose to physiology many of the secret mysteries of the most distinctive, seductive, and suggestive characteristic of humanity.

MUCOUS MEMBRANE, GLANDS, BLOOD-VESSELS, AND NERVES OF THE LARYNX.

The contour of the larynx, externally and internally, is covered by mucous membrane continued from that of the mouth and pharynx. It differs in thickness and degree of adhesion to subjacent parts. It is exceedingly thin and closely adherent on the free borders of the true vocal cords; thin, but less adherent in the sac of Hilton; loosely adherent to the false vocal cords; thicker and closely adherent on the posterior face of the epiglottis, and on the inner faces of the vocal processes; less adherent to the anterior surface of the epiglottis; very loosely attached to the ary-epiglottic folds and to the arytenoidal walls, which parts are thus extremely liable to become infiltrated, so that the inner surfaces almost touch, producing œdema of the larynx, or, as it is improperly termed, œdema of the glottis.

The epithelium is the ciliated variety found covering the whole mucous respiratory tract, except a narrow stripe of the squamous epithelium of the pharynx, which mounts the larynx posteriorly, continues down the internal face of its posterior wall, and covers the free portion of the true vocal cord from one end to the other. On the inferior face of the cords the ciliated epithelium is again encountered.

The larynx is abundantly supplied with glands. We find them in the laryngeal pouches, the pyramidal sinuses, in the posterior wall, in the ary-epiglottic folds when near their arytenoidal attachments they are accumulated in the form of an L, and are called collectively the arytenoid glands; in the pad of the epiglottis, and isolated elsewhere; but there are none upon the true vocal cords. They are sometimes solitary, sometimes in clusters, and vary from the size of a poppy seed to that of a lentil.

The larynx is supplied with blood by branches from the superior and inferior laryngeal, and the crico-thyroid arteries.

The veins empty into the superior, middle, and inferior thyroid veins.

The nerves supplying the larynx are the superior, and inferior or recurrent laryngeal of the par vagum, with some filaments from the great sympathetic. The inferior laryngeal is the motor nerve, and supplies all the muscles except the crico-thyroid, which, with the mucous membrane, is supplied by the superior laryngeal, which also sends some fibres to the arytenoideus.

THE SULPHATE OF BEBEERINE IN UTERINE DISEASES.

By A. P. MERRILL, M.D.

It will scarcely be doubted that most of the uterine diseases which are treated by surgical remedies with such varying success, are due to, or accompanied by, engorgements of the diseased organ, arising from local and constitutional irritations, inviting into its tissues an undue determination of blood, the natural consequences of which are hypertrophy and derangement of function. According to the degree and duration of this diseased condition of the uterus, there is an increase, decrease, or suspension of secretion, swelling, pain, leucorrhœa, hæmorrhage, and possibly obstruction of the cervix uteri. Displacements are also consequences of this tumefaction, and these are facilitated by vaginal relaxation, which is a constant concomitant.

These are the diseases which have of late years so occupied the minds of uterine pathologists, and led to the invention of mechanical and surgical remedies almost without number. Besides the volumes which have been published on this subject, the medical journals are laden with essays and discussions; but the disagreements among able and distinguished physicians are such, that they who are dependent for their opinions upon the observations of others, are still at a loss to understand the true character of the disease, and the remedial power of the surgical treatment which is so confidently recommended. If, therefore, these morbid conditions of the uterus and its appendages may be relieved in any degree by curative measures which tend to supersede the use of the speculum, pessary, tent, caustic, leech, hysterotome, cervical dilator, and other surgical appliances revolting to female delicacy, it behoves the profession to inquire into their remedial virtues; and the object of this brief paper is, to recommend the sulphate of bebeerine to such scrutiny.

Having occasion, several years ago, to treat a married woman of nervous temperament for periodic fever and neuralgia, and finding that she suffered considerable inconvenience from the action of quinine, I was induced to try the effect of the sulphate of bebeerine as a substitute for it. Relief not being obtained, I proposed to withdraw the remedy, but she objected, saying, although it was of little service to her neuralgic pains, it had promptly relieved her of excessive menstruation, and she wished to keep the medicine by her to answer that indication as occasion might require. Several years subsequently this intelligent lady expressed to me her conviction that she owed to the use of this one remedy her relief from painful uterine disease of long standing, and also from the reproach of sterility.

The sulphate of bebeerine is a remedy for dysmenorrhœa, excessive menstruation, hemorrhage, leucorrhœa, and all uterine disorders dependent, in whole or in part, upon hypertrophy and hyperæmia of the uterus and its appendages. It exercises, also, a tonic power over the kidneys and bladder, and a restraining influence over blennorrhœal discharges. I prescribe it in pills, made up with syrup, in doses of five to twenty grains, and commonly employ aloes as an adjuvant remedy.

Original Lectures.

LECTURES ON PUERPERAL CONVULSIONS.

Delivered in Chicago Medical College,

By W. H. BYFORD, A.M., M.D.,

prof. of obstetrics, etc.

Lecture III.

Uterine symptoms are not uniform; sometimes there are none; for so far as we can judge by examination of the uterus, and observations of the manner of the patient or any complaint, labor in many cases does not commence before the convulsions. Rarely we meet with cases that recover from them and are not delivered for several weeks afterwards. The first case I ever saw, the patient, after having convulsions for twenty-four hours, and ten or twelve in number, recovered perfectly, and in five weeks afterwards was delivered of a fœtus that probably ceased to live at the time she had the convulsions. Where there are no uterine symptoms at first, labor is apt to commence soon after the convulsions become severe, and proceed slowly to a termination, or advance so tardily as not to be complete before a fatal termination of the disease. Again, we often meet with cases where labor is in active progress before the convulsions commence. Where this last is the condition of things, labor is not generally retarded, although occasionally it is brought to a complete stop. The symptoms may show themselves in the second or third stage of labor, or even after the whole process is finished. I knew one patient seized with these convulsions on the third day after delivery. Attacks after labor are more likely to take place very soon—in a few minutes, or a very few hours at most.

The diagnosis is not generally difficult after the affection is completely formed. In a practical point of view, it is quite important to diagnosticate the predisposition to this form of disease, and proper care will generally enable us to perceive the tendency in this direction when well marked. With the nervous and gastric derangement described above, there is œdema of the *upper* portion of the body, upper extremities, or face. While œdema of the legs and feet is more frequently produced by pressure upon the veins coming from the lower extremities, this symptom occurring in the last months or weeks of pregnancy in the upper part of the body, is almost invariably the effect of albuminuria. When this form of œdema shows itself, the urine should be subjected to tests for albumen. Whether uræmia is always present when there is albuminuria, and whether uræmia does not sometimes occur without albuminuria, are questions which have not been positively decided, so far as I know; but we can, with sufficient assurance, regard it as an available rule, that albuminuria indicates uræmia. If albumen is found in the urine, we should prove by tests that there is or is not a deficiency of urea and uric acid in the secretion. These two facts would show a predisposition to puerperal convulsions. The diagnosis, then, of the predisposition is made out by the presence of œdema of the upper part of the body, face, and limbs, albumen in the urine, and a deficiency of urea and uric acid. After the attack has supervened, the diagnosis, for the most part, lies between epilepsy, apoplexy, hysterical and puerperal convulsions. There may be other affections with which there is a possibility of confounding these convulsions. Epileptic convulsions very rarely occur under puerperal circumstances in epileptic patients, and when they do, the convulsive seizure is not repeated. Apoplexy is ushered in sometimes by convulsions of short duration, to which characteristic profound and prolonged coma succeed. The convulsions are not repeated, the patient does not soon become conscious as after the first paroxysm of puerperal convulsions, and there is almost constantly nausea and vomiting with apoplexy. When coma is of more than very temporary duration, there is congestion of the brain, either as the result of the convulsions or as a primary condition; hence, we have a combination of apoplexy and urœmic convulsions as a not unfrequent thing. I think, however, that apoplexy, uncomplicated with uræmia, is quite uncommon in the puerperal state. I remember to have seen only one instance. As I have endeavored to show, in speaking of symptoms, the supervention of this complication is, perhaps, the most frequent cause of death, and it is what must, if possible, be avoided. Hysterical convulsions are distinguishable from the uræmia by symptoms arising from an opposite state than those of apoplexy, constant consciousness, more or less complete, and want of coma properly speaking. In hysteric convulsions, the color of the face is not so deep, the paroxysm is not terminated by carbonic anæsthesia, which shows the existence of apnœa; there is, in fact, almost no embarrassment to the function of respiration in hysteria, while there constantly is in puerperal convulsions. In hysteric convulsions, the muscular contractions are not completely symmetrical, but one arm will be acting violently and the other firmly fixed, and the legs do not move synchronously like shocks that succeed the first general contraction in uræmic cases; and I hope I may be permitted to say, that in hysteria the mental manifestations are perversities of disposition instead of the real inebriety of the uræmic disease. We must remember that they may be complicated, so that in the beginning we may have hysterical symptoms, but these are soon obscured by those arising from congestion of the brain. Perhaps, as in the premonitory condition, the most important items in a clear diagnosis are albuminuria and œdema. Examinations of the urine should be made when practicable.

Prognosis.—This has reference, 1st, to the safety of the mother, and 2d, that of the child. According to Brann, 30 per cent. of the cases, under ordinary circumstances, prove fatal to the mother. My own observation leads me to a more favorable prognosis, and in the practice of my friends and myself, I think 25 would be a large estimate of the mortality of uræmic puerperal convulsions. The particular circumstances influencing the prognosis are various. One of the most important is the time of the attack; commencing before or in the early steps of labor makes the case more dangerous than if it takes place later, for, according to Brann, the accomplishment of labor causes a cessation of the convulsions in 37 per cent. of the cases, their amelioration in 31 per cent. more, and that about 32 per cent. continue without change. There is less danger in post-partum cases than those commencing during labor. Cases in which the inter-paroxysmal coma is profound and persistent, or the breathing and pulse are very much accelerated, or where the bronchiæ seem filled with mucus, and sibilant râle is heard over a large part, or, as is often the case, the whole of the chest, the prognosis is grave; as is also the case, should the convulsions recur frequently, less than every hour, or continue for a long time. Cerebral, pulmonary, and circulatory deviations are the guides to the prognosis. The nearer the breathing and pulse continue to the natural standard, the more favorable the prognosis; the greater their departure from it, in any respect, the greater the danger. This statement needs but very little qualification. The mortality to the *fœtus*, if I can judge from the cases that have come under my own observation, is greater than that to

the mother. I think at least half of the children born during puerperal convulsions were dead. The cause of this great mortality among the children is not clearly agreed upon by the profession. Some think the convulsive action of the uterus cramps the circulation, causing asphyxia. The most likely cause, I think, is the uræmia. I have known two well marked cases of uræmia where convulsions did not take place, but the fœti in both cases were dead-born. In most cases, so soon as the labor has terminated, and the convulsions cease, the albuminuria passes rapidly away, all evidences of uræmic poison disappear, and the patient uninterruptedly convalesces. At other times, several weeks elapse before the excretion returns to its normal state, when the convalescence is interrupted by the occurrence of dropsical accumulations, causing death or tedious recovery, or there may be waning or great nervous prostration and fever. Very early the damage done to the brain is so great as to leave some part of the body or limbs partially or wholly paralysed, or bronchial or pneumonic inflammation may be established sometimes, and not readily subside.

Reports of Hospitals.

BELLEVUE HOSPITAL.

SPEEDY UNION IN A FRACTURE OF THE TIBIA AND FIBULA.—DISLOCATION OF OS MAGNUM.

SERVICE OF DR. FRANK H. HAMILTON.

[Reported by D. M. Cory, M.D., House Surgeon.]

Mary Ann Barrett, æt. twenty-nine, was admitted to Bellevue Hospital, November 12, 1866. On the day of her admission she was thrown upon the sidewalk by a man, who violently kicked her in the left leg. She was immediately brought to the hospital; says her health and habits are pretty good, except that occasionally she indulges in a little strong drink. Condition of leg, swollen and painful; false motion laterally near junction of middle and lower thirds of leg, with projection anteriorly of end of upper fragment of the tibia. The line of fracture is oblique, extending, as is usually the case in fractures of this bone from direct violence, from above downwards, and from behind forwards. The fibula was broken in its upper third, but the extent of displacement could not be ascertained on account of the thickness of the tissues at this point. The leg was shortened about half an inch; otherwise little deformity.

Treatment.—The patient having been placed in bed, the fragments were replaced as accurately as possible by extension applied to the foot. The limb was then snugly placed in a fracture-box, well padded with oakum, and cold evaporating lotions applied to keep down the swelling.

November 16th.—To-day a single enveloping splint was cut from medium sole-leather, and after being soaked in hot water, was carefully moulded to the limb, embracing the entire foot and ankle. This was padded with cotton batting, inclosed in a sack of muslin of the exact shape and size of the splint, and the whole was confined by rollers applied very tightly.

November 17th.—It was to-day noticed, as the fingers were placed upon the point of fracture on the anterior aspect of the leg, that as the patient rose up in bed, the upper fragment would move downwards, and would return again when she was requested to lie down. To obviate this motion, the limb was suspended upon a crib, allowing it free motion in any direction. As the patient was in the habit of using stimulants occasionally, she was allowed two ounces of whiskey daily.

November 26th.—Since the last report, the patient has been allowed to sit up in bed. The rollers have been reapplied from time to time, so that firm and continual pressure might be kept upon the broken bone. To-day she was permitted to get out of bed and to go about the ward upon crutches. The apparatus was readjusted, and union was found to have taken place to a slight degree.

December 12th.—To-day, just one month after the injury, the splint was removed, and union was found to be *firm*. No motion whatever could be produced between the fragments. The swelling has almost entirely subsided, and the limb presents a perfectly symmetrical appearance. When accurately measured, shortening of only three-eighths of an inch was found to exist. To prevent any accident, the splint was reapplied loosely, and the patient allowed to go about as before.

December 16th.—All dressings were removed. The patient can bear considerable weight upon the limb; and as a little stiffness of the ankle-joint remains, she was advised to use it as much as possible.

The special interest attached to this case consists in the fact that speedy union can occur between two fragments of this bone, in which, according to the common experience of surgeons, union is so frequently delayed, by carefully adjusting the broken ends, and holding them firmly in position by the proper apparatus. There is no bone in the human body in which union is so often deferred to the eighth, tenth, or even sixteenth week, as in this bone. It is true, however, that examples of non-union, or a complete and final refusal to unite, are here very rare, showing that there is no natural inherent difficulty in the union of this bone, and that cases of delayed union can generally be referred to a defect in the apparatus used. To follow out the proper indications, it is necessary in the first place, after the side-splints or single splint, whichever is used, have been applied, to carefully adjust the bandage as often as it is in the least loosened either by the diminution of the swelling, or by other causes, so that firm and continual pressure may be kept upon the fragments. In the *second place*, the leg should be swung, to obviate in a great measure the sliding motion produced upon the fragments whenever the patient moves in bed. And in the *third place*, the splints should be made large enough to nearly meet over the spine of the tibia; for unless this is done, the fragments at this point have no support except by merely the roller as it passes around the splints to hold them in position; or what might obviate the difficulty still more, would be to apply an anterior and posterior leather splint, being careful in moulding and padding them, so that the anterior one would not excoriate the thin layer of tissue covering the bone, and the posterior one so that it would accurately fit the uneven surface upon the calf of the leg.

Bridget Malar, æt. twenty-eight, was admitted into the Bellevue Hospital, Nov. 19, 1866. On the day of her admission she fell down a flight of stairs, striking upon the dorsum of her left hand, and flexing it forcibly upon the forearm; she came immediately to the hospital. Condition of hand somewhat swollen and contused, and she is unable to close it. There is a marked prominence upon the dorsum on a line with the second metacarpal bone. At first it was supposed that this was the bone that was dislocated; but in comparing the relative position of this joint with the articulation of the first metacarpal bone with the trapesium, it was found to be the os magnum. Reduction was accomplished by extension upon the first and middle fingers, at the same

time pressure being made upon the bone itself, when suddenly it resumed its natural position. It is now a month after the accident. She still has some stiffness of the hand, and finds it difficult to grasp anything firmly; but she is rapidly regaining the use of it.

Note.—Cases of this kind are extremely rare, and none appear in the case-books at Bellevue Hospital. Dr. Hamilton has never seen one, although in his work on "Fractures and Dislocations" he quotes some few cases reported by English and French surgeons.

EXCISION OF SUPERIOR MAXILLA—LIGATURE OF COMMON CAROTID.

[Reported by Dr. CHRIVLER H. LUDLUM, House Surgeon.]

Catherine McCann, æt. 31, a native of Ireland, admitten August 17th, 1866. She first noticed a small swelling on the upper jaw twelve years ago, which gave her no trouble until four months ago, when it increased in size and became painful.

She entered the hospital June 20th, 1866, and the tumor was removed by Dr. Sayre on the same day. In a few days she was discharged, but the pain continued, and another tumor appeared at the site of the former. This increased rapidly in size, and at the time of her second admission (August 17th), the disease had invaded the whole left side of the jaw, and appeared at the mouth as a fungous, bleeding mass.

Sept. 5th.—Consultation held, and left common carotid ligated, and the left half of the upper jaw and malar bone removed by Dr. Hamilton. But little blood was lost during the operation; the cavity stuffed with lint.

Sept. 6th.—Semi-comatose; does not speak, but swallows regularly; catheterized twice to-day. Hemiplegia of the right side, and paralysis of the left instead of the right side of the face.

Sept. 11th.—Slight hæmorrhage from the roof of the mouth, which recurred occasionally until the close of the month. It was checked by persulphate of iron.

Oct. 3d.—The cavity left by the removal of the bone filled with a fungous mass, which bleeds readily when touched. Glands at the angle of the jaw are swollen and tender.

She continued to grow weaker, and died Nov. 5th, at 6 A. M.

Post-mortem 30 hours after death—rigor mortis not marked, body emaciated.

Brain—The left hemisphere had patches of white softening, especially towards its posterior aspect. The substance of the brain had a purplish-white color, and, except at these softened points, was harder than normal.

Thorax: Lungs—The right lung had numerous abscesses scattered through its substance, but no deposits of cancer were detected. The left lung was healthy.

Abdomen—Liver studded with numerous deposits of cancer, varying in size from a pea to a hazel-nut. There were one or two deposits of the same character in the spleen.

Kidneys contracted, having evidently undergone granular degeneration.

LOCAL ANÆSTHESIA IN VETERINARY SURGERY.—Dr. A. Liautard, V. S., New York College of Veterinary Surgeons, reports the successful use of local anæsthesia in operations upon the horse. Absolute ether was employed upon two subjects: one for the extirpation of a large fibrous tumor of the chest, and the other for the opening of an abscess, while upon another the operation of neurotomy was performed with the greatest ease by the rhigolene spray.

Progress of Medical Science.

NEW METHOD OF EMPLOYING HEAT AS A RESUSCITATING AGENT.—Dr. Joseph G. Richardson, of Union Springs, N.Y., details (*Am. Jour. Med. Sci.*) a very interesting case of resuscitation of a still-born infant, by a novel application of heat. The idea of employing this method was suggested to him by a paper by Dr. B. W. Richardson, of London, on the uses of heat as an invigorator. The infant alluded to was born on the morning of the 18th of February, and at the time made no effort to respire, although a feeble pulsation was perceptible at the præcordia. The usual treatment of hot bath, cold affusion, etc., was of little if any avail, and finally it occurred to Dr. R. to try warming the blood in the peripheric veins, and afterwards forcing it back to the heart. To carry out this idea, the little one was properly protected in blankets, and placed upon the hearth of a large cooking-stove. "The effect of this treatment," says Dr. R., "was almost miraculous; the heart's pulsation, which, in spite of three hours' labor with artificial respiration and its adjuncts, had continued feeble and uncertain, grew rapidly full and energetic; the respiration, which had commenced again to prolong its intervals, changed its gasping character, became continuous, and although groaning, otherwise almost normal; and to crown all, the limbs, which had heretofore dangled, relaxed, from the apparently lifeless trunk, soon exhibited signs of vitality, which, beginning first, after some ten minutes' roasting, with a slight tremulous movement of the extensors of the right leg, gradually traversed the entire muscular system, until the whole tiny frame shook like an aspen leaf, quivering, one might almost think, with too rude a blast of the breath of life. I remained with the infant for an hour or so longer, and experienced the intense satisfaction of observing a continued, though tardy improvement, the skin gradually losing its blue color, and assuming the pink tint of a healthy new-born babe's. The physician being unfortunately compelled to leave the case in charge of an ignorant nurse, who, contrary to directions, had insisted upon administering some molasses and water, death took place in the effort at deglutition." The success attending this new adaptation of an old principle should claim the attention of every practitioner. We have no doubt that many lives may thereby be saved.

DISLOCATION OF THE RADIUS AND ULNA FORWARDS AT THE ELBOW WITHOUT FRACTURE.—A case of this very rare dislocation occurred at *University College Hospital* the week before last, during the frost. A strong young man, of twenty years of age, slipped down on the pavement, falling on his left elbow. On getting up he found he could scarcely move the elbow, which was so painful that he applied immediately at the hospital. On examining him about twenty minutes after the fall, Mr. J. W. Langmore, the house-surgeon, found that there was some swelling and a slight bruise over the prominence of the elbow, with but little swelling elsewhere. The arm was bent at an angle of about 130°, but could be flexed to a right angle and straightened to about 160°, although all movement gave the patient great pain. The forearm was about three-quarters of an inch longer than its fellow. The condyles of the humerus were nearly on a level with the olecranon, which was displaced forwards, the tendon of the triceps muscle being very tightly stretched round the end of the humerus. The sigmoid notch could be felt. The head of the radius could also be felt in front of the lower end of the humerus. Mr. Langmore replaced the ulna by bend-

ing the elbow across his knee, and then, as the radius was still dislocated, he reduced it by pressure on its head, whilst good extension was made by assistants. The arm was then put on a straight splint and an evaporating lotion applied. A certain amount of heat and swelling ensued, but by the fourth day this subsided, and the joint was quite movable.—*Lancet.*

EXTIRPATION OF THE TONSILS.—The *Nashville Journal of Medicine and Surgery* quotes Guersant as follows: "If in young subjects whose throats are narrowed, the hæmorrhage following excision of tonsils is not likely to be troublesome, it is not the same in patients of eighteen or twenty years old. Hæmorrhage, in such cases, is frequently to be feared, because the hypertrophy is of longer standing, and the vessels are more developed. I have operated upon more than a thousand children, and I can scarcely remember three who had sufficient hæmorrhage to cause me any anxiety. On the contrary, I have operated upon twelve or fifteen adults, and I must say that at least four or five of them caused me great uneasiness, and that I could only stop the hæmorrhage by the use of the hot iron or the perchloride of iron. I should say, then, that the operation is beneficial in proportion to the youth of the patient, and grave in proportion to his advance in age."

STEAM TO THE CAVITY OF THE TYMPANUM.—Dr. Hagen, of Leipsic, recommends the use of steam, which is generated in a glass flask, as an application to the cavity of the tympanum, though the eustachian tube, by means of Politzer's method of inflating the cavity of the tympanum (blowing in the air through the nose, while the patient swallows, with the mouth closed). It is said to cause no pain, and to be useful in the case of children suffering from acute inflammation of the middle ear. The manœuvre is to be repeated from three to five times every two or three days.—*Wiener Med. Presse.*

PRURITUS PUDENDI.—Prof. N. S. Davis, of Chicago, recommends as a local application for this troublesome affection, the following lotion, which may also be injected, in small quantity, into the vagina each night and morning:—A solution of borate of soda (borax] ʒ iij., and sulphate of morphia 20 grains in a pint of water.

POISONING FROM NICOTINE.—A patient was brought to the General Hospital in Vienna, in the wards under Professor Oppolzer's care, in what seemed to be a tetanic condition, having been found so on his bed, when he had lain down to rest a short time. He was senseless, but after the injection of ¼ gr. of morphia in solution, in about an hour he began to move his head and gradually his body, without, however, coming to consciousness. An enema of water and vinegar was then administered, when vomiting ensued, and with a small amount of greenish fluid, eight or ten small pieces of tobacco leaves were ejected.

The patient recovered, and said that he had been in the habit of chewing an ordinary cigar, and had lain down with some of the leaves in his mouth. Albumen was found in the urine, the next day after admission, but none subsequently. The patient left the hospital on the seventh day after admission.

MODIFICATION OF THE OPERATION FOR STRABISMUS. By DR. R. LOIBRICH, OF PARIS.—I lift up a fold of the conjunctiva, in tenotomy of the sectus internus, on the lower ends of the insertion of the muscle, cut it with the scissors, pass in through the opening between the conjunctiva and the capsule of tenon; divide these two membranes carefully from each other, up to the plica semilunaris, and separate these, as well as the caruncle, from the parts lying behind. After the entire capsular portion, which is so important in the setting back (sücklagering) of the muscle, is completely independent of the conjunctiva, I divide the insertion of the muscle from the conjunctiva in the usual way, and lengthen the incision in the capsule made with the tenotome, above and below the more extensively, according as I wish the setting back of the muscle to be great or little. I then close the conjunctival wounds with a suture.

The advantages of my method are as follows:—1. A greater freedom and a much larger space for the regulation of distribution (of the effect) of the operation for squint. 2. The avoidance of a sinking in of the caruncle, and of every trace of cicatricial formation, which the ordinary tenotomy sometimes leaves. 3. The avoidance of more than two operations on the same patient, and more than one on the same eye.—*Archiv für Ophthalmologie.*

A CASE OF DISLOCATION OF THE GLOBE OF THE EYE, CAUSED BY THE HORN OF A COW, MISTAKEN FOR AN ENUCLEATION. By PROFESSOR VON BEEKER, OF HELSINGFORS.—The peasant woman A. S., æt. thirty-two, consulted me last September, on account of her left eye. Seeing the sunken eyelid and the half-opened palpebral fissure, which seemed empty, I asked how she had lost her eye? She answered, that the eye had not been removed or lost, as all the people said to whom she had shown it, but that it was simply driven into the head.

She stated, that in June she had gone out, as was her habit, to get the cow. The cow was ugly, and hooked at one of the children who was with her. The mother ran to save her child, but as she bent over to seize it, the cow ran her horn into the left eye, so that she sank to the ground, although it gave her great pain. She rose up, put a handkerchief around her head, and walked to the house, about one hundred steps off; only a very little blood ran from the eye and nose. Once there, she lost her strength. She began to vomit; had severe headache and vertigo, and soon lost her consciousness, so that she did not know what happened for four days. When her senses returned the wound was closed, and the eye itself scarcely pained at all. While sick, she had continuous and severe headache, and could only take liquid food. The left cheek was very much swollen—no sensation, or scarcely any, in it. There was toothache. She could not see well with the right eye, especially near at hand; straining the eye caused headache. In three weeks she was able to go about. Present condition of left eye: Along the supra-orbital border is a cicatrix 25 mm. long; it begins at a point vertically over the puncta and extends, becoming 2–3 mm. broad, to the outer commissure of the lids. The cicatrix is movable, not adherent to the bone beneath. The upper lid is very much sunken in; levator palpebræ still lifts it, so that the palpebral fissure can be opened about 5 mm. The lower lid is stretched tensely in front of the orbital cavity, but is relaxed below, towards the cheeks. The conjunctiva smooth, only slightly hyperæmic. If the lower lid is drawn down, when the reflection of conjunctiva is generally seen, we find an external and internal fold of conjunctiva reclining against the mucous membrane coming from the upper lid, and thereby having a deceptive similarity to the funnel-shaped space left after enucleation. The point of the finger may be introduced into the open palpebral fissure, without any resistance, almost 20 mm. The lachrymal apparatus is normal. If the two lower folds of conjunctiva with the lid are drawn down as much as possible, we may see scarcely two lines over

the supra-orbital border, the upper border of the cornea, the bluish-grey iris, and even a small portion of the moderately enlarged pupil, all healthy and normal. In the upper portion of the visual field of this eye the patient counts fingers with complete certainty. The ocular conjunctiva next to the cornea is white and normal. No movability of the globe to be detected. In right eye the acuteness of vision is one-half; glasses do not improve it. Field of vision defective in outer portion. The ophthalmoscope shows the media to be clear; the retinal blood-vessels a little dilated. Vision has lately improved. Some paralysis of the muscles of the left side of the face. The teeth are said to be sensitive. Sensation exists everywhere in the integument; it is a little blunted in the left lower lid. Both orbital cavities are at the same height.

The patient was put under the influence of chloroform, in order to effect a more thorough examination. The finger introduced around the upper half of the equator of the globe showed that no foreign body was pressing the eye down. From the trochlea of the obliquus superior I felt the belly of the muscle; the eye was then rotated inwards and downwards; the globe was very firmly adherent to the inner and lower side of the orbit. After removing the tendinous adhesions in the neighborhood of the lachrymal sac, I was able to examine the inner portion of the infra-orbital border; there was no unevenness in the bone. I did not attempt to replace the globe, on account of the time which had elapsed, three and a half months, which had caused firm adhesions. Besides, with reposition we could not hope for congruous movements of the globes. If I had been able to dissect up the eye, and place it in its former position, the strabismus would have probably produced extremely unpleasant double images. * * * The concussion or tension of the optic nerve was continued upon the right side, and caused the defect on the outer part of the field of vision, and also the paralysis of accommodation. As to the third pair, the branch going to the levator is unharmed; the other may have been torn by the horn, since there is no movability in the globe.—*Archiv für Ophthalmologie*, xii. *Band, Abtheilung* II.

Action of Baryta and Oxalates.—A pupil of Hoppe-Seyler, several years ago, attributed the toxical action of baryta and its soluble compounds to the accumulation of insoluble sulphate in the capillaries of the lungs, thus causing a mechanical impediment to the process of respiration (*Am. Drug Circ.*). This is denied by Dr. Cyon, who, from a series of recent experiments, feels justified to call the effects of baryta a paralysis of the central organs of the nervous system of the heart, probably by means of its nervous appendages. A similar effect can be traced in the action of oxalic acid and its compounds. The matter is of importance in so far as doubts had arisen as to how far sulphuric acid for baryta, and lime for oxalic acid, might be administered with safety in cases of poisoning.—*Druggists' Circular.*

Othatomata, or Hæmatomata of the Auricle.—At a meeting of the General Association of St. Petersburg Physicians, held April 19, 1866, Dr. Gehewe spoke at some length on Othatomata of insane patients, with a demonstration of some pathological preparations of these tumors. The blood tumor of the ear was first described by F. Bird, of Siegburg, in 1833. Leubuscher, of Halle, called it Erysipelas of the Auricle. Fischer, however, gave the tumors the name of *Othatomata* in 1848. There are still synonyms used, *Hæmatomata* or *Otitis in the Insane.* There is no doubt that the affection occurs also in the sane, although cases have been much more frequently observed among the insane. The symptoms are as follows: There is formed in the fossa between the *helix* and *anti-helix*, or in the *concha*, never on the lobe of the ear, a livid reddish tumor, which in its beginning is generally unobserved, since the patients do not complain of it, and it easily escapes the attention of the physician. It develops quite rapidly to the size of a bean, a walnut, or even to that of a pigeon's egg. The tumor is tense, elastic to the touch, has quite a distinct contour, and on severe pressure is generally painful. To this latter symptom, as in general in the subjective symptoms of the insane, too much credence cannot be given, since sensation is either morbidly increased or diminished in their cases.

The tumor remains in this condition for some days or weeks, finally loses its redness and heat, collapses, becomes doughy; its integument becomes wrinkled, and it either passes into a normal condition, or, in the greater number of cases, leading to deformity of the auricle, either by shrinking or hypertrophy.

Virchow's recent observations have decided with certainty that the hæmatoma of the auricle occurs in exactly the same way, and under the same conditions, as the *cephalatomata* of the newly born—that is, from mechanical, and often traumatic causes. These causes produce a separation of the perichondrium from the cartilage similar in both cases, only with this difference, says Virchow, that in the *othatomata* pieces of cartilage generally remain adherent on certain spots of the loosened perichondrium. Through the investigations of *Meckel*, the conclusion was formed that these portions of the cartilage were new formations, which still further confirmed the analogy with *Cephalatomata.*

In cephalatomata the so called bony ring, which gave to the finger the false sensation that there was a hole in the skull, is only a deposit of periosteum, which first begins to form on those points where the periosteum is elevated from the bone. The periosteum continues to make this bony deposit and finally forms a bony shell over the hæmatoma. This shell is a proliferation of the inner layer of periosteum, from which the new bony layers proceed. Then the function of periosteum—the nourishment of bone—ceases with the separation of the layers by an extravasation of blood; and thus there arises a connected layer of flakes or scales of cartilage and bone. Etiology.—The older authors ascribed the existence of the *othatomata* to a blood dyscrasia, or to an "especial predisposition to an erysipelatous nature." Gudden was the first one (in 1860) to give the mechanico-traumatic origin. His reference to the deformed ears of the heads of the old Grecian pugilists, seen in the Munich gallery, and the literature of the subject, is interesting. The observation has been made, that in the insane the left ear is more apt to be affected with this tumor than the right—this being the one more liable to be struck by the right hand. Gudden, however, goes too far, when he makes the attendants alone responsible for the appearance of othatomata. It may occur from injuries done to the ears by the patients themselves. His idea as to the origin of these tumors is substantiated by the fact, that on a better organization of insane asylums—that is, with a better class of attendants—othatomata are less frequently seen.

The treatment is expectant. On opening the tumor, a viscid bloody fluid or pure blood is evacuated. The wound soon heals.

The belief that *othatomata* generally occur in patients who are hopelessly insane, is not confirmed by the author, who relates several cases, which lead to the opinion that the appearance of the tumors has nothing to do with the prognosis.—*St. Petersburger Medicinische Zeitschrift*, 1866, 4–5 *Heft.*

OUR THERAPEUTICS.

OUR system of therapeutics is getting in a bad way. The physician of the present day has coaxed himself into the comfortable belief that nature is such a trusty handmaid, and is capable of doing so much for him, that he is inclined to leave almost everything that refers to the treatment of disease entirely in her hands. The opinion that the *vis medicatrix naturæ* can, under almost all circumstances, be implicitly trusted, has become so prevalent, that we can hardly be surprised that the important department of therapeutics is almost entirely thrust out in the cold.

It is within the recollection of many that the custom of dosing our patients almost to the death was a duly honored one, and the physician who would not order a score of remedies in a single prescription, notwithstanding he might in so doing openly defy all laws of compatibility, was behind the age; was in fact an unreliable, if not unsafe practitioner. We have certainly learned something since then, but in our zeal to correct the mistakes of our predecessors we have invited a dangerous reaction. We say dangerous reaction, because we believe it to be so in that tendency to neglect, which it has already engendered, and may still further encourage.

Experience and observation have taught us to believe that many of the diseases which heretofore were controllable by certain remedies, have been found self-limited. This fact, in the face of it, carries the conviction to the mind of every medical man that medicines are useless in such maladies, except so far as they may be employed against any complication that may arise. So far, then, we have learned much that is valuable, and are certainly in a measure on our guard against any meddlesome interference.

But are we not, on the other hand, in danger of doing too little? Are we not getting into the habit of being indifferent pilots, caring more to learn the characters and customs of the port to which we are allowing our desperate case to drift, than to study the course of some new and better channel? This we fear is the case. We accustom ourselves to believe that such and such diseases are incurable or uncontrollable, and almost the whole of our attention is given to the pathology of the affection and to conjectures upon the correctness of a diagnosis.

Pathology, as a study, is perhaps more attractive than any other department. The brilliant discoveries that have been made through its agency in increasing our knowledge of the nature of different diseases, are sufficient to account for this. But despite its allurements, there is no reason why it should be studied to the exclusion of other equally important branches, in which that of therapeutics should hold no mean rank.

There seems to be such a lack of disposition to study this particular branch, and to treat it with that detail, care, and conservatism, which it most assuredly claims, that we are in danger of becoming, if not hobbyists, certainly routinists. If this tendency be not checked, we shall soon shut our eyes to everything but two or three remedies, and be ready to use them in our treatment of all diseases. Indeed, that time seems nearly to have arrived. The medical professor will now lecture upon a particular disease; he will give its history, characters, the method of diagnosticating it from others which it may resemble; but when he comes to the treatment of this very interesting affection, how common is it for him to dispose of it in the most cursory manner as if in fact it was of the least importance. The student who has faithfully followed this lecture, has filled perhaps pages of his note-book with the account of the disease, but under the head of treatment, a simple line suffices to write the stereotyped phrase, "*Whiskey*, *Quinine*, and *Iron*."

Therapeutics is not at present, we must acknowledge, a very inviting study. It is so much behind its sister departments that a great amount of labor is required before we can make an even start. But this should not discourage us. Most of our works are made up of much that is useless; of too many remedies that are obsolete, and which have qualities assigned them of which they are as innocent as the paper upon which they are printed; but neither the knowledge of this fact, nor the appreciation of the uncertainty attending the administration of vaunted specifics, nor the conflicting theories regarding the actions of medicines, should allow the science of therapeutics to remain in its present ignominious position.

Far from improving our knowledge of therapeutics as we should, we are virtually going further from our destined goal. We have not only reduced our agents to the smallest possible number, but we do not seem to be disposed to study well even these few. A physician who wishes to prescribe iron, or quinine, would rather for convenience' sake order it contained in some pill compounded in a foreign country, than figure out the ingredients in such respective proportions as will meet the indications of an individual case. It may be possible that these manufactured pills are carefully made up, even though they are compounded on a wholesale scale; but the habit of using them in the indiscriminate

manner now so generally indulged in is, to say the least, unscientific. When a single ingredient is used in a pill or other menstrua, it is not so bad, for then if the manufacturer is reliable, the probability is that the physician will not be working so much in the dark, as he must then recollect what he is using; but when several materials are compounded, is it likely that one not careful enough to write for his own proportion of ingredients would be apt to keep in mind those of another which may be offered him?

All this thoughtlessness in prescribing is, we are convinced, the result of a want of a proper appreciation of the potency of medicines, and their value, when properly used, in modifying disease. The young physician has sneered at the "old fogy;" but the question seriously comes up, concerning the present treatment of disease, whether the "old fogy," who has parted with his idol calomel, cannot return the compliment. In our zeal to support the claims of the advocates of non-medication, we have discarded too many old and well tried remedies, and our only excuse is a flimsy one at best, that their employment heretofore was but the exponent of hobbyism. The manifestation of that same spirit is apparent in the distrust with which every new remedy is viewed, many refusing to give such an article a fair trial, even though its recommendations for favor emanate from a most responsible source. The consequence is, that our list of remedies is being quite rapidly reduced; and if we continue in our present course Materia Medicas will be looked upon as cumberers of the shelf, and our therapeutics will be in the deplorable position of the traditional Job's turkey with one feather in its tail, and that feather will be called—*stimulation*.

THE recent death by chloroform, at Bellevue Hospital, has added another to the list of the victims of anæsthesia. No blame can be attached to any one connected with the case. The gentleman who administered the anæsthetic; used all ordinary care, and the operator, when the patient began to sink, employed every means which science could suggest, or skill put in practice, to ward off the fatal result. All this goes towards establishing the fact that chloroform is a dangerous article, and that we should be continually on our guard against the constantly recurring accidents which are due to its use.

IN another column is published a circular letter in reference to the holding of a convention of medical teachers. The different subjects which are to be brought up for discussion are of immense importance, especially those rererring to this establishment of a uniform rate of fees, and the increased of the lecture term, and the number of professorships. We cannot commend them too strongly to the serious consideration of the different faculties of our colleges, and hope that the call of the committee will meet with a very hearty and general response.

Reviews.

"CONSIDERATIONS GÉNÉRALES SUR L'ENSEMBLE DU SERVICE DES ALIÉNÉS DU DEPARTEMENT DE LA SEINE, SOUVENIRS À M. LE SÉNATEUR, PRÉFET DE LA SEINE." By M. GIRARD DE CAILLEUX, Inspector-General of Asylums for that Department. "RAPPORT SUR LES ALIÉNÉS DE LA SEINE TRAITÉS DANS LES ASILES DE BICETRE ET DE LA SALPÈTRIÈRE." By the same Author. Also, the "RAPPORT ET PROCES-VERBAUX DE LA COMMISSION POUR L'AMÉLIORATION ET LES RÉFORMES À OPERER DANS LE SERVICE DES ALIÉNÉS," Signed M. GIRARD DE CAILLEUX, as Secretary of the Commission.

DURING the last year, a special inquiry has been instituted by the French government into the state of the great hospitals for the insane in Paris, the Bicêtre and the Salpêtrière, and generally into the condition of all the lunatics belonging to the populous department of the Seine. The results of this inquiry are of special interest to us at the present time, when the minds of the profession, as well as the public generally, have been turned to the subject, and when State Legislation is invoked for better provision for our insane poor. It will be seen that this inquiry has terminated in the adoption of reforms of the greatest magnitude, involving the entire subversion of the existing establishments, and the construction of several new asylums to accommodate all the insane of the department, many of whom have hitherto been distributed in the asylums of other departments, more or less remote from the one to which they belonged.

The Commission consisted of three eminent senators, the Procureur-General, one Councillor of State, and Drs. Paul Dubois, Dean of the Faculty of Medicine, Husson, and M. Girard de Cailleux. The Board, at its several sittings, examined numerous witnesses, including several of the most eminent alienist physicians in France, and presented, by its chairman, M. Ferdinand Barrot, an able report of the results of its labors. This report furnishes a very clear insight into the state of lunacy in France generally, and especially in the Department of the Seine; and, at the same time, portrays strongly the aspects of the great lunatic hospitals of the capital, and the reforms which the commissioners suggest.

The report embraces a wide range of topics, such as the "*State of Lunacy in France generally;*" "*Of the Bicêtre;*" "*Of the Salpêtrière;*" "*Medical Service;*" "*Occupations;*" "*Surveillance and Directions;*" "*Religious Services;*" "*Mechanical Restraint;*" *Mortality;*" "*State of the Insane in Provincial Asylums;*" "*Reforms Proposed,*" *&c.**

We have only space for a few items. Most of the physicians visit their patients at eight or half-past eight in the morning, some few at six. When speaking of the medical service, generally, the commissioners take occasion to insist on the greater amount of observation and attention, and therefore *on the longer time* necessary in treating the insane than in prescribing for an equal number of patients in a general hospital, on account of the additional psychological element, which, to render

* In 1884 the insane in France were reckoned, by M. Ferries, at about 12,000, including 8,390 in hospitals, and 3,600 wandering at large, or living with their families, or shut up in prison. Whilst, in 1818, there were only eight institutions for lunatics, in 1886 their number had increased to thirty-nine, viz.: One State Asylum, and thirty-eight departmental. Besides these there were twenty-one hospitals with lunatic wards, and forty-five private asylums. In this year (1886) the insane were numbered at 60,238; of whom 26,289 were under treatment in institutions. The proportion of this total to the then population of France was as 1 to 1,370, whilst in the Department of the Seine the proportion of lunatics under treatment to the population was as 1 to 487.

treatment successful, must be taken into especial consideration, in cases of insanity. This fact has long been recognised both in Great Britain and our own country, where those who have charge of the insane generally reside in the buildings; but with the exception of the *internes*, or *resident pupils*, the attending physicians of all the insane hospitals of Paris reside without the establishments. In regard to *food*, the *dietary* of the two hospitals, Bicêtre and Salpêtrière, is reported to be abundant and of excellent quality, but a regret is expressed that meat is furnished only once a day; the *dress* of the patients, it is stated, leaves much to be desired, the clothes being badly made, and badly fitted, and a source of vexation and annoyance to their wearers. No provision is made for keeping separate the clothes of individual patients; hence there is a want of interest in their preservation, of a feeling of satisfaction in their cleanliness, and of a useful stimulus to order and management or economy. The means of repression or *discipline* resorted to are prolonged baths, the douche, the camisole, temporary seclusion, close cells, and the deprivation of tobacco.

In regard to *occupation*, at the Bicêtre, the insane are occupied in agricultural work, in horticulture, shoemaking, carpentry, cartwright's work and building operations, in painting, blacksmith's work and washing, in brewing, in the piggeries, and in household work. Of 980 male lunatics, 205 of them are employed. At the Salpêtrière, the women are employed in cutting out and making clothes, in household work, and in lint-making. Of 1,431, 827 were employed in these different ways. Of these, as many as 126 were engaged in making lint, 539 in needle-work, and only one in washing. The excess of sedentary work is regretted, and the washing of clothes is recommended as a "suitable work for the women, and favorable for treatment." In regard to *surveillance*, the number of attendants of the Bicêtre is fixed at 116 or 1 to 8.52; at the Salpêtrière at 146, or 1 to 9.10. About 180 men and 230 women attend service on Sundays and great fast-days.

In regard to *mechanical restraint*, while the Commission admit that there are now and then cases of insanity which demand the employment of the camisole or seclusion as exceptional means of treatment, yet it is stated that restraint is much too largely employed at the Parisian hospitals for the insane. At the Bicêtre 27 patients were found wearing the camisole, a proportion to the 980 inmates of 1 in 36. But besides these coerced by the camisole, many others were fastened to their beds. At the Salpêtrière only 18 patients were in any way restrained; which, in the population of 1431, was 1 in 79. *None were confined in their rooms during the day.* With reference to their classification in the two establishments, there were at the

	980	1,427

The mean ratio of registered *recoveries*, between 1839 and 1858, was 1 in 6.27 at the Bicêtre, and 1 in 4.02 at the Salpêtrière. However, among such recoveries are reckoned some who have only been improved. The *mortality* has amounted, on an average, between 1839 and 1858, at the Bicêtre, to 1 in 3.66, and at the Salpêtrière to 1 in 3.29. Several reasons are assigned for this excessive mortality, but the most important would seem to be, first: the confinement of the insane under new and unhealthy conditions, where their physical, physiological, and moral habits are suddenly interrupted and changed; and second, the vicious hygienic condition of the localities in which the establishments are placed. The *seats of disease* causing death are, in the order of frequency, the head, the abdomen, and the chest.

The cost of the patients is thirty cents a day, for the men, and twenty-five cents a day for the women, but the Commission state that this might be reduced for both sexes to twenty cents a day, if the patients were placed in properly organized asylums.

The general result of the inquiry is, that the Bicêtre and Salpêtrière are inadequate to their purposes, and need to be radically reformed. Their several sections are defective, and too often vicious both in their architectural and medical arrangements, and the different quarters deficient in unity of co-ordination. Some of them are neither safe nor salubrious for their inmates. The dormitories are overcrowded, and classification incomplete. The refractory are not under adequate control and supervision, the use of restraint is much in excess, the number of dirty patients far too great, the medical service imperfect, *surveillance* difficult and badly organized, the means of occupation insufficient, the clothing leaving much to be desired, and there is an intermixing of inmates prejudicial in itself and contrary to law, which demands a remedy as soon as possible.

We pass over many interesting details, to quote some of the *reforms proposed.* The following is a *resumé* of the recommendations and conclusions arrived at by the Commission:

I. The creation of special asylums for the insane of the department of the Seine. II. The administration of these asylums directly by the departmental authorities. III. The construction of a central asylum to be situated in Paris, for the reception of all forms of insanity, but especially of acute and recent cases, and in connexion with it a system of clinical instruction. IV. The institution of an office for the admission of patients, to be annexed to the central asylum, where reputed lunatics may be examined and their distribution be determined. V. The erection of asylums out of Paris, and at such distances that the relations between the patients and their friends may be easily maintained. VI. The establishment of especial asylums for insane epileptics and idiots. VII. The new asylums to be so constructed as to receive lunatics of both sexes, yet so as to secure an absolute separation between the two. VIII. The erection of establishments, in connexion with the asylums, for the reception of pensioners at fixed charges; such buildings, however, to be thoroughly detached. IX. The direction of the asylums to be intrusted, if practicable, to one individual, having entire control both over their general government and medical superintendence. X. *The employment of the insane in various useful arts, and particularly in out-door operations.* XI. *The adoption of the system of committing such cases of mental disorder as present no danger to public order and security, to the care of their friends in their own homes.*"

Such are the most important measures of reform agreed on by the commission, after many sittings, and calling to their assistance several of the most eminent alienist physicians of France. The actual number of insane in the department to be provided for, at the date of the commission, was 4216; but taking into consideration the rapid increase of their number of late years, it was resolved to assume 6,000 as the sum-total for which accommodation should be provided.

As to the dimensions which the asylums should have, it was generally agreed that the maximum number to

be received for treatment should be 600, and that, consequently, *ten* new asylums would be needed for the department.

In the case of the Central Asylum in Paris, it was considered desirable to subdivide it into four sections of 150 each, and to appoint a non-resident physician to each, who should give regular clinical instruction and lectures to the medical students of Paris; a resident physician is also to superintend it, and the bureau of admissions. M. Girard de Cailleaux expressed his opinion that, in a scientific point of view, *the smaller an asylum the better it is;* for that the indications of science are to restore to the lunatic, as far as possible, his social position and relations (the *vie de famille*), by supplying in their absence the contact with him of persons of sound mind, and of kind and benevolent character; and that, moreover, the physician can devote the more time to his patients the less numerous they are. The strict deductions from scientific grounds must, however, yield to a certain extent to economical considerations; and he was convinced that not more than 500 or 600 patients should be placed in the same asylum, inclusive of 100 pensioners of various classes, paying respectively $146, $240, $360, and $480, or more per annum. With such an organization, an asylum, costing in construction not more than $500 per patient, exclusive of the cost of site, should by proper management, by agricultural and industrial labor, and by a regulation of the admissions in accordance with the views of the Legislature, cover the interest chargeable on the capital expended in its construction. *This result experience has shown practicable.* At the Insane Asylum at Auxerre, it is stated, the expenditure would have been covered by the receipts, had not an increased number of imbecile gratuitous patients been admitted, and the daily charge for maintenance been reduced in the case of the poor, from one franc fifteen centimes to one franc per day. The commission dwell with much emphasis upon the importance of restoring to the insane, *the usual influences and surroundings of domestic family life* (*vie de famille*), and in order to effect this, of placing them under the influence in the highest degree attainable, of persons of sound mind, a result, as is stated in the Report, to be arrived at only *by division, by instituting small sections or quarters, and by separating the various classes of patients.* It is by such means that the moral status of the insane can be improved, that discipline can be enforced, however chronic their malady may be, and *it is with regard to chronic lunatics that the moralizing influence is the most difficult and more frequently the most useful.* Moreover, every chronic case is liable to pass through the successive phases of excitement, collapse, filthy habits, tranquillity, and turbulence, along with incidental maladies. Hence arises the necessity of establishing, even in asylums that receive only chronic cases, those five fundamental classes, or categories, which are recognised by the French legal enactments relative to the construction of asylums.

The Commission remark that, "if regard be had to the indications of science, as must be indeed, since it is desired to carry out a reform, and to offer to the intelligence of Europe an example worthy of imitation, there must be a division of the insane, *to escape the error of erecting asylums of too large dimensions, and not to follow the example of the English, who constructed fortresses for their unfortunate people, in spite of the impotent protestations of science and experience.* There is nothing, moreover, to be gained in respect to economy in these mischievous agglomerations, if the principles of classification enunciated are adopted. Indeed, in such great asylums, the error now seen in the asylums of the Seine becomes repeated, of dividing the services and of multiplying the general costs, at the expense of breaking the unity of direction and management. True progress is bound up with the multiplication of asylums and their distribution under one sole control." In regard to the proportion of *cells* (equivalent, we suppose, to the *padded rooms* of the English asylums), one to forty of the population was deemed sufficient. We read of no instance where *cribs*, so-called, are used or recommended for the purpose of confining the insane; nor is there any evidence that they have ever been employed for this purpose except in some American asylums.

The asylum of Auxerre, which was visited by the Commissioners, is to be adopted as the model in the construction of the new institutions projected. With reference to their medical staff, it was decided that, in the case of the asylums without Paris, the medical officer should be also the superintendent or director, and have under his control a *steward*, a *secretary*, and a *receiver*. The principles recognised in the management of our own asylums were fully adopted by the Commission, namely, that unity of thought, of interest, of responsibility, of power, and action, is an essential condition for the successful treatment of the insane, and for the good government of an asylum. The compound nature of man, of soul and body, demands, for the most successful treatment of insanity, the combination of pharmaceutical, hygienic, and moral means. To act mentally on the insane, the physician must have complete authority over the attendants and others about his patients, and there is nothing to prevent him engaging in the pursuit of the science of his profession, inasmuch as he can have assistance from others in many administrative details, in the preparation of prescriptions, in conducting correspondence, etc.

In discussing the question of the practicability of providing separately for the curable and incurable, a majority of the Commission voted in the affirmative. It was agreed that about four-fifths of the insane belong to the class of chronic or incurable, and it was conceded generally that those who had not recovered at the end of two years, were not likely to do so. That some few, out of a considerable number, should get well after that period, was held to be no argument against the attempt to separate recent and acute cases of insanity from chronic and probably incurable, particularly as in asylums occupied by the latter, the hope need not be ignored, and the means of cure would not be wanting. On the other hand, it was admitted, *that the separation is desirable on economic grounds, and the cure of recent cases could more thoroughly be cared for in specially adapted asylums of small size, and with a full complement of medical aid.* Moreover, it would be a simple expedient to remove any cases from an asylum for chronic patients to that for recent, or *vice versâ*, when thought desirable; and it would not be necessary to call any of the institutions *asylums for incurables.* No difference of opinion prevailed in regard to the expediency of separating the insane epileptics and idiots from other persons of unsound mind, and of placing them in a special asylum.

The above *resumé* of the reports of this able and learned Commission, will convey some idea, however imperfect, of the magnificent general scheme about to be carried out in the department of the Seine for the management of this most unfortunate class of beings; and it will not be long before we shall find a series of asylums, built after the most approved models, furnished with every appliance for the well-being, the treatment, and recovery of their suffering inmates. In comparison with this well developed scheme of asylums, construction, and management, much of what has been

done in England and in this country, must be looked upon as ill-contrived and ill-executed, and needing, ere long, the reformer's hand.

THE FUNCTIONS AND DISORDERS OF THE REPRODUCTIVE ORGANS IN CHILDHOOD, YOUTH, ADULT AGE AND ADVANCED LIFE. By WILLIAM ACTON, M.R.C.S., late Surgeon to the Islington Dispensary, etc., etc. 2d Amer. from 4th London ed. Phila.: Lindsay & Blakiston. 1867. 8vo., pp. 291.

THE fourth edition of Mr. Acton's most excellent work is before us. The author treats the subject in reference to four important periods of human life, viz. childhood, youth, adult age, and advanced life. He has very carefully incorporated in the treatise what new matter has accumulated since the last edition, besides using the lights of collateral sciences.

As an instance of thoroughness of treatment, we may mention that he does not hesitate to view his subject from a religious stand-point, even referring to sermons preached by Jeremy Taylor and others. The text is enlivened by quotations, one of which, from Lord Bacon, regarding continence, from its aptness as well as sound morality, we cannot refrain from transferring to our own pages. "He that preferred Helena, quitted the gifts of Juno and Pallas; for whosoever esteemeth too much of amorous affection, quitteth both riches and wisdom. . . . They do best, who, if they cannot but admit love, yet make it keep quarter."

Masturbation, Continence, Incontinence, true and false Impotence, Satyriasis, Spermatorrhœa, etc., are fully and ably discussed. The author inclines to the belief that *absolute continence* can be maintained without injury to the individual, thus rebuking the advocates of sexual congress as a cure for sexual torments. He shows that religion, morality, and science may, without other aids, succeed, when working in unison. The painful subject of masturbation is treated with the author's usual firmness and delicacy, and we simply dismiss it with the remark that it does credit alike to the author's head and heart.

We are glad also to see that Mr. Acton pays due deference to the opinion that spermatorrhœa, long the bugbear of the nervous and bulwark of quackery, is rather a disease of the mind than the body, and that the fears of the patient should be allayed as speedily as possible, strict attention at the same time being paid to exercise and diet without any resort to medication, except in desperate cases.

Altogether, the work is to be deemed a classic in its line, from the fact that the only lights which the author has followed in investigation, are those of sound philosophy and science.

METHOMANIA; A Treatise on Alcoholic Poisoning. By ALBERT DAY, M.D., Superintendent and Physician of Washington Home, Boston; with an Appendix, by H. R. STORER, Prof, etc. Boston: James Campbell. 1867. 18mo. pp. 70.

THIS little volume is a treatise on those poisons which first stimulate, then narcotize. The author has had ample means to thoroughly investigate his subject, having had over two thousand cases under his care, a great many of which were suffering under one of the different forms of mania à potu. These, he truly says, vary in symptoms, according as the patient may have been habitually intoxicated a considerable length of time, or have indulged in a paroxysm of drunkenness. The symptoms are well described, but there is not that amount of newness about the volume which we could expect from a treatise more strictly scientific. It is really intended as a warning to the young against the vice of drunkenness, and its attendant crimes—a form of disease which we all know is frightfully prevalent. Looking at the work from a humanitarian point of view, we cannot but hope that it may meet with all the success it deserves, and at the same time are well satisfied that those who have not larger and more elaborate treatises in their libraries can find in its pages much practical information. Perhaps the only objectionable feature about the work is the appendix, by Dr. Storer, wherein he warmly praises Dr. Day for his unflagging zeal in this branch of medical treatment, as well as the Legislature of Massachusetts for passing a law to incorporate an asylum for inebriates, all of which we think unnecessary to the discussion of the subject.

Reports of Societies.

N. Y. PATHOLOGICAL SOCIETY.

STATED MEETING, Nov. 28, 1866.

DR. FRANK H. HAMILTON in the Chair.

RESECTION OF FEMUR FOR MORBUS COXARIUS.

DR. ROGERS exhibited the head and neck of the left femur of a boy eight years of age. Three years ago the patient began to complain of the ordinary symptoms of morbus coxarius, for which he was treated by extension, falling in the mean time into the hands of various individuals. Next he entered the Institution for the Ruptured and Crippled, where he remained under treatment for the greater part of two years. The case came to the Demilt Dispensary a year ago this month. The boy at that time was very much emaciated, there being extensive suppuration from a row of sinuses extending in a longitudinal direction for half the distance down the external and posterior aspect of the thigh. He had hectic fever, night sweats, and his strength was failing so fast that it was not thought he would last very long. On consultation an operation for the removal of the diseased bone was considered advisable, and was performed by Dr. Rogers.

Not only were the head and neck of the bone removed, but a portion of the shaft, in an oblique direction, which had become denuded of periosteum by the track which the pus had taken to escape from the cavity of the joint. At the time the operation was performed there was scarcely anything of the limb left but skin and bone, but by careful treatment the muscles acquired a considerable development, and the patient being presented to the Society along with the specimen gave ample evidence of being able to move the limb with considerable freedom. The operation had been performed only a year since, and the patient had been going to school for the past six months, and was able with the help of a cane to walk with ease. The affected limb was shortened about an inch. Slight rotation outwards and inwards had been preserved to him, and flexion was tolerably free, although of course limited.

Dr. POST called attention to the existence of a small sequestrum at the upper part of the shaft, just below the neck and on the inner side of the bone, which was no larger than robin's shot. He also remarked that there was a remarkable degree of porosity in the remnant of the neck.

DR. ROGERS, in answer to a question, remarked that the treatment subsequent to his operation was substantially the same as that for hip disease by extension. At the time that the patient was allowed to bear his weight upon the limb, aided by crutches, there was no difference in length between the two extremities, but as he began to use it the thigh-bone shoved up a little. Dr. R. did not think that the difference would have been so great, had his injunctions with reference to the gradual use of the

limb been followed. Passive motion of the limb was early resorted to, and to this circumstance was doubtless due the amount of mobility already referred to. He stated that the sinuses on the back part of the thigh were serious obstacles to recovery, and continued to exist long after the wound of the operation had granulated and healed.

Dr. Post thought that the specimen gave evidence of more absorption of the neck than the head.

Dr. Rogers remarked that the displacement of the capsular ligament first described by Dr. Geo. K. Smith, of Brooklyn, as belonging to these cases, was found in the present instance.

A BULLET IN THE HEART FOR TWENTY YEARS.

Dr. Hamilton presented, on behalf of Dr. Balch, a heart, in the substance of which a rifle ball had been imbedded for twenty years of the life of the patient. The following is the history of the case as furnished by the gentleman owning the specimen:

In the year 1840, John Kelley, a boy fourteen years of age, was employed at Chatham Four Corners, Columbia co., N. Y., in driving a horse cart hauling gravel, for the construction of the railroad from Albany to Boston.

One night while in bed in the upper part of a shanty, which was constructed for the workmen, a target rifle was fired from a hill back of the house; the bullet passed through two roof boards and a board partition, and entered Kelley's right shoulder through the upper border of the trapezius muscle about two inches from the acromion process. The physicians who were called probed the wound, and thought they felt the ball about four inches from the point of entrance, the course of the missile being downwards and a little inwards. They decided to let the bullet remain, as they thought an operation was more dangerous than non-interference.

There was a little hæmorrhage and no great local disturbance at the time. In about six weeks the boy was able to resume his work. He gradually gained his health, and to all appearances was perfectly well. He afterwards removed to Clinton co., N. Y., married, and became the father of several children.

In 1845, he was attacked with pneumonia, situated in the upper lobe of the right lung. Dr. Orvill Terry of Redford, Clinton co., N. Y. attended him during this seizure and also his last. During the illness of 1845, for the first time, was noticed a very tumultuous action of the heart, which remained after his recovery from the pneumonia, and continued to increase up to the time of his death, June 14th, 1860; twenty years after being shot, and fifteen after disease of the heart manifested itself.

Kelley's last illness was the result of exposure to the cold waters of a mountain brook, he having gone into them for the purpose of washing sheep a few days before his death. Congestion of the right lung was the result of the exposure. The heart's action became exceedingly violent, and four or five days closed the scene. Two days before his death his right arm and hand became purple and cold.

The post-mortem examination was commenced with the view of finding the bullet and of examining the diseased condition of the heart and lungs.

I dissected the neck; found the right internal jugular vein enlarged, the right external jugular I could not find; I found, however, something that I took to be the remains of the external jugular entering the internal jugular (which is an anomaly of that vein). In the right subclavian artery, pericardium, and other places, I found atheromatous deposits. The upper lobe of the right lung I found congested; other parts of the lung normal; no tubercles anywhere. The heart was enlarged, soft, and flabby; it having undergone Quain's fatty degeneration. The pericardium was very adherent, more particularly on the right side. I had not yet found the ball. A hard lump was felt in the right ventricle, near the apex of the heart; on introducing my finger into the ventricle through the vena cava and right auricle, I ascertained that the lump was in the wall of the right ventricle near the septum, at the most pendent part of the ventricle. On looking carefully at the outer surface of the organ, I could find no cicatrix. I then cut down upon the lump and found it to be a leaden bullet, somewhat flattened, and encysted in the wall of the heart.

Dr. Hamilton remarked that the case had been already published in the *American Journal of Medical Sciences*, but he was not aware that the specimen had ever been presented to any medical society. He stated in this connexion that Dr. S. S. Purple, of this city, in a paper on wounds of the heart, published in the May number of 1855, of the *N. Y. Medical Monthly*, reported twelve examples of gunshot wounds of this organ, in which the patients survived from two days to six years. In the case reported by Fugi the patient lived fourteen days with a ball in the pericardium. Dr. Hopkins, of Ohio, has reported a case in which the patient survived fifteen days with a pistol ball in the wall of the left ventricle. Carnochan's patient, the notorious Poole, lived eleven days with a pistol ball encysted in the walls of the heart. In the case reported by Dr. Randall of Ohio, the patient died on the sixty-seventh day, and three shots were found in the right ventricle and in the right auricle; the wounds having cicatrized. In the *Indian Annals of Medical Sciences* a man is said to have survived ten weeks with a musket ball in the cavity of the left ventricle. Fournie records the history of a man, who, wounded by a ball, fell as if he were dead. Three months after, he suffered from severe palpitations, but which nearly disappeared after three years. He died six years after the receipt of the injury, from some malady unconnected with his injury; and the ball was found lodged in the right ventricle, near the tip, and resting on the septum medium.

Dr. Peaslee did not see why Dr. Balch's patient might not have lived much longer with the ball in his heart, as it did not seem as if death was the direct result of its presence in that organ. The palpitation which the patient suffered was in his opinion probably increased by the extra labor thrown upon a heart already crippled. Beyond this increase of the heart's action to overcome the weight of the ball, and the effect of its presence in somewhat embarrassing the action of the organ, there was nothing unusual. He observed that the missile in this instance had perforated the muscular wall, and was lying in contact with the attached surface of the endocardium.

Dr. Rogers thought that inasmuch as there were no signs of a cicatrix upon the walls of the ventricle, the ball might have found its way to that situation by entering one of the large vessels, dropping down, and passing though the endocardium.

Dr. Hamilton confessed that he had formed no theory upon the subject, but stated that he believed Dr. Balch was of the opinion that the missile had entered the heart from within.

Dr. Jacobi asked how such a circumstance as the wound of so large a vessel could be conceived without the occurrence of hæmorrhage?

Dr. Hamilton, in this connexion, referred to a case on record in which the carotid artery was wounded by a ball which plugged up the proximal side. The patient died of secondary hæmorrhage from the distal extremity.

Dr. Post remarked that he had reported a somewhat similar case of wound of the vertebral artery, death

taking place several days after from secondary hæmorrhage. He also stated it as a well established fact that wounds of the large vessels near the heart were much more promptly fatal than similar wounds of the walls of the heart itself.

Dr. Flint was of the opinion that a ball of the size in the specimen presented would, if it entered the cavity of the ventricle, be driven by the current of blood into the pulmonary artery.

Dr. Peaslee suggested that, supposing the ball entered the heart from within, the only available vessel that could be wounded for such a purpose would be the superior vena cava.

Dr. Finnell stated that in Poole's case there was no sign of a cicatrix upon the external surface of the heart. A careful search was made for some track of a ball, but none being found, the heart was placed aside and the examination continued. At length one of the gentlemen present only by accident discovered the ball in the substance of the heart.

Dr. Hamilton remarked that an interesting point in Dr. Balch's case was that no syncope followed the receipt of the injury to so vital an organ. In Poole's case, the shock was so violent that his comrades at first thought him dead; so in the case of the man who survived six years.

SYPHILITIC NECROSIS OF SKULL.

Dr. Hamilton presented an example of syphilitic necrosis of the skull. The specimen consisted of the crown of the skull, and was made up principally of the upper portions of the two parietal bones. It was removed by operation on the Monday preceding. He exhibited the specimen more for the purpose of bringing out a point of some interest, which was in effect that the bone, although extensively necrosed and worm-eaten, was really not dead at the time of its removal. At the time of the operation he found this portion of bony tissue firmly adherent by extensive granulations to healthy parts beneath; the granulations extending into the very interior of the diploic tissue. When the bone was separated from these connexions, the hæmorrhage was very profuse, so that in a very short time the patient lost nearly a pint of blood. He believed that the existence of these granulations explained the reason why the bone was absorbed; in fact, he considered that these vessels were the only agents by which absorption could be carried on.

The specimen also showed that the disease was confined to the periosteum. A considerable portion of bone, which though dead had not shown any signs of separating, still remained. The patient did well after the operation, and at the time of reporting the case was able to sit up.

PLEURISY IN AN INFANT.

Dr. Lewis Smith exhibited a specimen of pleurisy in an infant. The patient died at the end of three months and fifteen days, without having any conspicuous symptoms, and without the usual courtesy of a diagnosis. On post-mortem examination the left pleural cavity was nearly empty, the lung occupying only about one-sixth of the space allotted to it. This organ was firmly bound down by fibrous material, which also covered the costal pleura. On attempting to inflate the lung, the air escaped though a small opening in the centre of a solidification in the upper lobe. This solidification was not due to pneumonia, but probably to pulmonary apoplexy.

He also presented a second specimen of pleurisy in an infant who died at the age of seven months. In this instance a diagnosis was made of pleuro-pneumonia, which was confirmed by a post-mortem examination. The left lung was found to be the seat of the pneumonia, and the overlying pleura was not only inflamed, but that portion of the membrane extending beyond the margin of the inflamed lung.

The Society then adjourned.

EAST RIVER MEDICAL ASSOCIATION.

Adjourned Meeting, January 4, 1867.

Dr. V. Morse, President, in the Chair.

HEREDITARY TENDENCY TO THE HÆMORRHAGIC DIATHESIS.

Dr. Thoms read a paper with the above caption.

Cullen has observed that children are most subject to the diseases of the parents whom they most resemble; it is rational, however, to suppose that the mother exerts the more powerful influence in giving an impetus to the tendency. In support of this latter view, it should be remembered that in the crossing of animals, the relative influence of the two sexes is quite manifest; e. g. a mule, the issue of the mare and the ass, is incomparably larger and stronger than the product of a pair where the sexual relations are reversed.

The laws governing the transmission of diseases are various, and it is only by aid of exact and numerous observations, which from necessity can only be slowly accumulated, that we are enabled to appreciate the relative frequency of a particular disease in individuals exposed to a suspected hereditary taint, and in those who are not obnoxious to any such influence.

In consideration of hereditary hæmorrhagic diathesis, the solution of the problem is to be sought for rather by carefully studying the course of the lives of the children themselves, than by tracing out the morbid genealogical tendencies of ancestors.

Dr. T. then quoted the following quaint account of a family predisposition to hæmorrhage, reported by Drs. William and Samuel Bual, and which was published in the *Physico-Medical Transactions* in 1817.

"The subjects of the following account were the descendants of the Rev. Timothy Collins, the first pastor of the town of Litchfield, Conn. So far as we have been able to ascertain, the first manifestation of hæmorrhagic predisposition was in the male children of his son Oliver. We cannot, by diligent inquiry, learn that there were any indications of this disposition in any of their predecessors on either the male or female side. Oliver Collins had several sisters and brothers who had children to the second and third generation, in none of whom do we find that there has been any manifestation of the hæmorrhagic trait.

"Oliver Collins had four sons and two daughters. In all of the sons this predisposition discovered itself in an extreme degree, from early infancy, and continued through life. Three of them bled to death. It is not known where the fourth is, or whether he is alive. Two of them, though frequently reduced by hæmorrhage to a state of exhaustion threatening the extinction of life, lived to adult age. One of them eventually died from hæmorrhage induced by the extraction of a tooth; the other from hæmorrhage following a slight contusion of the fore-finger. The one which died in childhood, bled to death from a slight laceration of the tongue by the teeth, occasioned by a stroke under the chin. It is related of these persons, that after experience had taught them their liability to hæmorrhage, they acquired an extreme sensibility in relation to their danger, shuddering at the sight of edge tools, and avoiding with the utmost caution all exposure to them.

"The next appearance of a disposition to bleeding was

in the son of Mrs. Baldwin, one of Oliver Collins's daughters. It may be noticed here that the other daughter, Mrs. Garty, has both male and female descendants, in none of whom has this hæmorrhagic constitution appeared; Mrs. Baldwin's son possessed it in an equal degree with his uncles. He lived, we believe, till near the age of puberty, when he bled to death from a slight wound caused by the fall of a pewter plate on his foot.

"The last instances in which this family characteristic has discovered itself are the male children of Mrs. Kilburn (a daughter of Mrs. Baldwin). She had four sons, in all of whom a tendency to bleeding has been strongly marked since early infancy. In her daughter it has been absent. Two of her sons have already, in childhood, fallen victims to hæmorrhage. Another son, who was drowned at the age of eighteen months, had exhibited the hæmorrhagic predisposition as strongly as did his brothers; and once bled almost to death from a rupture of the frænum of the upper lip. The death of one of the boys was caused by a hæmorrhage proceeding from a wound produced by a stab penetrating the bottom of the foot. He died in about forty-eight hours from the time of receiving the injury. His brother died after extreme exhaustion induced by nasal bleeding. He had an abscess in the leg, which discharged a short time previous to his death, and which may have co-operated with the loss of blood, in exhausting the powers of life. The only surviving son has been frequently reduced to a state of exhaustion threatening life, by hæmorrhage from the nostrils, small lacerations of the frænum of the upper lip, and slight wounds in various parts of the body.

* * * * * *

With regard to the Kilburn branch of the Collins family, but little remains to be said. Indeed, a number of years have elapsed since the deaths of the other victims of this remarkable predisposition. We may, however, premise the general remark that we cannot discover that there has been, in any instance, in the female connexions of the Collins family, any evidence of hæmorrhagic trait.

"It may be remarked of the Kilburn boys, that there is not only a strong disposition to hæmorrhage when the blood-vessels are wounded, but that there is also a tendency as strongly marked to plethora and spontaneous hæmorrhage. They have all of them, and we believe the same to be true of their bleeding predecessors, had frequent hæmorrhage from the nostrils, gums, and particularly from the frænum of the upper lip.

"In all instances slight contusions are followed by extensive ecchymosis, and a great degree of tumefaction. From a slight contusion on one of the knees of Kilburn's surviving son, received eighteen months since, an enormous tumefaction ensued, with rigidity of the joint, from which he is not yet perfectly recovered. The boys, when beginning to walk, have for a number of months perpetual ecchymosis about the nates, from the contusions received from falling on them. The plethoric state of the system which takes place when any considerable time elapses without hæmorrhage, is evidenced by a flushing of the face, a sense of fulness about the head, indisposition to active exertion, and all the usual symptoms of plethora. Their countenances have always a sallow puffed hue, not unlike that which is observable in those who have recently had fevers from the operations of marsh effluvia.

"This sallowness is not absent when the blood-vessels have a plethoric fulness; the face is flushed, exhibiting a complexion strikingly different from the red and white tints of health. When the vessels are drained by hæmorrhage the countenance is sallow and pale in the extreme. We have never witnessed in the male part of the Kilburn branch, any wounds of sufficient size to have the current of blood, in case it was arterial, assume the *per saltum* motion; but the strong impetus with which the blood is discharged, and the powerful resistance which it opposes to all remedies, whether mechanical or of other kinds, in whatever manner applied, would seem to be strong evidence that the blood is arterial. The blood is not destitute of coagulability; large coagula are frequently formed about the orifice of the wounds, but the impetus with which the blood flows overcomes their too feeble resistance. When by any means the hæmorrhage is suppressed, the part above usually becomes distended, livid, and intolerably painful, so that relief is obtained only by permitting a recurrence of the bleeding. Slight wounds have, in some instances, healed by adhesive inflammation. We have not discovered any malformation or unnatural distribution of the blood-vessels generally, nor in the valvular construction of the veins particularly. It has been noticed in the Kilburn boys, and it may exist in all, that they have had during the debility existing after hæmorrhage depraved appetites; one of them was disposed to eat sand, another common earth.

"It will be observed in this report, that all the cases which have occurred, have been in the male line, and it has disclosed itself at an early age, and abating as age advances. This state seems often to fluctuate in the same patient; a scratch at one time threatening fatal loss of blood, at another scarcely attracting attention. In some, distinct periods of remission and exacerbation may be observed. At the latter times the patient is subject to frequent attacks of pain and swelling, with ecchymosis of the wrist, ankles, and knee joint, attended with fever. These symptoms continue about a fortnight, and then disappear, with subsidence of the swelling and removal of the ecchymosis."

This diathesis, then, has many points of resemblance to both the scrofulous and the scorbutic. The most prominent signs are an obvious delicacy of system; usually a fair complexion; a thin transparency of skin; irritability of circulation at all times, conjoined with occasional febrile accessions; a tendency to ecchymosis from the slightest cause, as also to hæmorrhagic oozing from mucous surfaces.

The causes would seem to be twofold; a morbid condition of the blood, and also of the capillaries. In the cases similar to these under consideration, the blood is described as "thin and ichorous, deficient in the due proportion of fibrin, and in the power of coagulation; more especially it is incapable, even when wholly at rest, of forming a dense and firm coagulum." In consequence of such change in the fluid, there ensues an undue tendency to congestion of the capillaries; so that these vessels, when cut, are not only filled with blood incapable of affording the best hemostatic agent —coagulation, but also contain an amount of that fluid greater than normal. The blood itself is probably altered in quality, but the nature of the change is not accurately known. Dissolution of the corpuscles or fibrin, so much insisted on by some writers, is not really present. The corpuscles seem to be deficient in number, and the liquor sanguinis is in excess; but these peculiarities may be the result and not the cause of the hæmorrhage.

The capillaries and minute arterial twigs are also at fault. When examined, the latter seems to be devoid of the middle coat, the former is of a thin and feeble appearance and unusually capacious. It may be that the middle coat is deficient, as some suppose, but more probably it exists, though in a defective state, and certainly impaired in contractility and tone. In conse-

quence, the other component parts of the natural hæmostatics are equally defective as to the power of coagulation. The cut vessel contracts and retracts scarcely, if at all; remaining open and unshrunk, passively pouring out its thin contents. Further, the vascular coats are friable and easily torn. Slight bruises produce serious ecchymosis, coughing may induce hæmoptysis, a sneeze brings on epistaxis, and extravasations in the internal cavities are not unlikely to follow slight causes.

The Treatment necessarily becomes prophylactic, every precaution being taken to prevent any and every solution of continuity. Resembling, as it does, scrofula, the usual tonics adopted in the treatment of that disease will be of service; but perseverance in their use is especially essential. Not being unlike scurvy, in certain of its symptoms, citric acid naturally suggests itself as a remedy, and this he would be inclined to put to a pretty thorough test. Occasionally, brisk purgative doses of sulphate of soda will prove beneficial, in two ways; as a hydragogue, diminishing the amount of serum in the blood, and as a chemical salt, exerting some peculiar power over the blood, compelling its coagulation.

When the crisis of hæmorrhage has occurred, attention should be directed to the improvement of the state of the blood, as well as the condition of the capillaries, with a view to hæmostatic results. We should if possible increase the proportion of fibrin, and as a means the induction of inflammation may be attempted at a distance from the bleeding part. Then again a derivative effect on the source of hæmorrhage is effected only at the expense of time, which in these cases is of course not without value. But the induction of true inflammation, in view of the reaction in store, may be seriously questioned here. Simple irritants and dry cupping, however, are not open to such objections; and therefore may be unhesitatingly employed. For the sake of promoting a state of nausea and depression, as most likely to favor the desired hæmostatic result, abstinence from food and drink may be insisted on. But should our first efforts fail, and the bleeding continue, we may be driven to the use of non-stimulant nutriments in small quantities, as soup, animal jelly, &c., omitting aqueous fluids, as tending to bring about a plethora of thin blood. Wine, brandy, and all other stimulants, unless at the eleventh hour, are not likely to exercise any other than a baneful influence. But possessed as we are of so little power in contributing an increase to the amount of fibrin, we may endeavor to turn that which is already in the system to good account. Subacetate of lead and opium may then be administered in full and sustained doses. In the event of the failure of these last we may fall back upon the sulphate of alum and potass., in doses of fifteen to twenty grains, upon gallic acid in doses of twelve grains frequently repeated, or upon matico in infusion, as the stomach may tolerate. For chemical reasons, the sulphate of soda cannot be given in conjunction with the acetate of lead.

Nauseants not only moderate the heart's action, but plainly favor coagulation of the blood. Ipecacuanha or tartar emetic, in doses short of actual emesis, at the commencement of the case are therefore expedient; for it is then our aim to artificially induce that depression which is analogous to faintness from syncope without the concomitant of loss of blood, which, of course, becomes alarming in an exact ratio to its period of continuance.

A capricious shifting from one remedy to another, in haste and confusion, is to be avoided: the medical attendant is called upon in these cases to persevere in one well selected plan until results have begun to tell.

Our second indication is directed to the state of the vessels. Of internal remedies, opium is likely to exercise a beneficial influence indirectly. In mucous surfaces, turpentine, gallic acid, matico, the fluid nitrate of mercury, and the sulphate of iron, have often proved highly advantageous, and may be employed as local adjuvants to the general means of arrest. For general application, some prefer nitrate of silver, not as a mere styptic to be trusted to alone, but as preliminary and adjuvant to pressure, which is to be considered the principal local means of arrest. The nitrate is used so as to restrain the flow, and permit the apex of a graduated compress to be retained in position by a bandage, etc., to be laid in a dry bed. A great amount of pressure must be carefully avoided, for both part and system are intolerant of this; ecchymosis, sloughing, and ulceration, with much constitutional disturbance of a low and irritable type, will certainly follow, and in a short time blood will burst forth, from a wider surface and with a more willing flow than before.

The actual cautery has naturally been much employed in desperate cases; but the resulting eschar arrests the flow only temporarily, since the process of detachment is, in such cases, both early and rapid, and the ulceration, opening up parts devoid of plastic exudation, opens up a larger surface for a new and more aggravated hæmorrhage. Besides this, the parts are by its use rendered incapable of bearing subsequent application of pressure. Deligation of the principal arterial trunks fails because the oozing is from capillaries.

The operation of transfusion as a last resort should not be delayed until the patient is quite in extremis. The making of an additional wound, which in its turn may assume an indomitable tendency to bleed, is a risk to be appreciated, although experience has shown that such is not invariably the result.

Dr. A. K. Gardner related a case illustrative of the hæmorrhagic diathesis, as manifested in the person of a German lady, who had consulted him about five or six years ago for a deeply jaundiced complexion, accompanied with an almost intolerable itching of the whole body. She had freely availed herself of the benefits reputed to belong to the German Springs, and from thence had repaired to London to test the virtues of a *new* liver specific, Podophyllin! She returned to this city with a recovered complexion, but with little if any mitigation of the itching. It was then noticed that there were certain layers of a yellow formation in the palmar creases, and near the inner canthus of both eyes, which, by competent authority, were thought to be due to the presence of fat. Last June she projected a visit to the White Mountains, and in the course of her journey was seized with an exhausting diarrhœa, *not* cholera. In obedience to a telegram Dr. G. found her in a perfectly powerless condition, coughing out a stringy mucus, with an aphthous tongue, a relaxed uvula, and emaciated to the last degree. In a word, she was suffering from spinal meningitis after the diarrhœa, complicated with other troublesome symptoms. He advised stimulants, a chlorate of potash gargle, and left her in charge of a physician who had come up for a vacation.

She recovered but partially, when she was, not long afterwards, seized with a hæmorrhage from an old, defective tooth, which had been not at all interfered with. Perchloride of iron, matico, nitrate of silver, and collodion, had all proved unavailing. He was not aware, however, that it was an instance of hereditary tendency. The case of a child might also be adduced in further illustration of this diathesis. This little patient, not many hours after birth, exhibited upon its occiput distinct ecchymoses not traceable to any accident or anomaly in labor, these came to implicate other por-

tions of the surface; and the child, who, by the way, was remarkable for an extremely pellucid skin and resembled a wax-doll very much in appearance, finally died at the end of a week.

A third case was that of a child which was seen in consultation, where almost fatal hæmorrhage occurred from lancing the gums. This was arrested by applications of the Liquor Ferri Persulphati, but died after four days from purpura hæmorrhagica, which appeared over various portions of the trunk and limbs.

Dr. Barry, without, of course, attempting to cite the cases as parallel with those of Purpura Hæmorrhagica, had succeeded in arresting the troublesome bleeding sometimes consequent upon the extraction of a tooth, by a cork plug shaped like a cone and armed with a pledget of raw cotton saturated with an astringent solution. He forced this well down into the cavity and had the satisfaction of seeing an effectual arrest of these very troublesome hæmorrhages, after the usual remedies had failed.

Dr. Burke was of the opinion that somehow or other the hæmorrhagic diathesis was associated with a jaundiced complexion. The intolerable itching which accompanies the latter condition was well marked in a patient now under his charge.

The meeting then adjourned.

Correspondence.

EXTRA-UTERINE FŒTATION, AND THE METHOD OF ARRESTING THE ATTENDANT HÆMORRHAGE.

To the Editor of the Medical Record.

Sir—I find that your report of my remarks made at the Pathological, on the occasion of presenting some specimens of extra-uterine fœtation, as published in the Record of the 1st inst., has led some of my obstetric friends into a misapprehension of the object of the treatment there proposed, of the accidents of this abnormal condition. The chirurgical procedure "advocated," was directed exclusively to the saving of the life of the woman from the destructive hæmorrhage following a rupture of the fœtal cyst—an accident uniformly fatal, so far as I know.

It would appear, however, that those remarks, and the proposed treatment, have been accepted by some of your readers as applicable to the management of the extra-uterine fœtus in general—an impression that I desire to correct, by distinctly stating, that no interference with an extra-uterine fœtus was then, nor at any other time, advocated by me; except so far as it might become necessary in the proposed operation for arresting the flow of blood from the torn edges of the ruptured cyst, and in the removal of the effused blood, fluids, etc, from the peritoneal cavity. As I contemplate bringing this matter before the profession in a detailed manner at an early day, I will simply add here, that I then stated, that where all the usual signs of pregnancy have been present during a period of some weeks or months, and are suddenly attended by all the rational signs of hæmorrhage into the peritoneal cavity, it is more than probable that an extra-uterine fœtal cyst has burst, and that blood to a fatal amount is escaping from the torn tissues and vessels. To remove all doubt as to the locality of the effused blood, I further proposed the use of the trocar; and if by its aid the presence of blood in the peritoneal sac be demonstrated, to open freely the cavity of the belly, secure the bleeding pedicle or vessels by ligature, clean out carefully the peritoneal cavity, and close it up.

This operation would naturally include the removal of such portions of the fœtal cyst as would be likely to slough, but should not, in my opinion, include any more.

In the majority of cases, like those I presented to the Society on the occasion alluded to, the ligature would be required to include the fallopian tube on one or on both sides of the cyst, and often the ligament of the ovary; and doubtless all the tissues included and strangulated by these ligatures, would require removal.

In conclusion, I desire to say, that gastrotomy for the removal of an extra-uterine fœtus for any reason, is a subject that I have never proposed to advocate; but when the life of the woman is next to certain to be lost by reason of hæmorrhage from a torn fœtal cyst, I do distinctly propose to make an effort to save it, by ligating the *whole bleeding pedicle*, be it great or small, and at all periods of gestation.

Respectfully,

Stephen Rogers.

No. 232 West Thirty-fourth street.

CASE OF STRYCHNINE POISONING TREATED WITH CAMPHOR AND CHLOROFORM.

To the Editor of the Medical Record.

Sir—I beg leave to report the following case, which I hope may be found of some little interest.

On the 20th of November, 1866, at 12 M., I was requested to see H. F——, a young man residing in this village, who, it was said, had, an hour and a half previously, taken four (4) grains of crystals of strychnine for the purpose of self-destruction.

I found him on the floor of the salesroom of one of our drug-stores lying on his back, and suffering intensely from spasms easily excited upon the lightest touch or motion made in his presence. He was perfectly conscious, and obstinately persisted in refusing to take any remedy which was proposed to avert a fatal termination. Doctors Sweeney and Nichols, who had arrived a few minutes earlier, had made every exertion to induce him to take an emetic, but failed. He had, however, taken a small quantity of camphor and commenced the inhalation of chloroform, which he seemed very willing to continue on account of the relief it gave from suffering. One small dose of camphor was by great exertion taken, but soon the muscles of deglutition became permanently rigid; any further attempt to use internal remedies was utterly useless. For about three hours the chloroform was continued, the spasms for the last half hour gradually gaining in severity, until 3 P.M. One general convulsion came up which seemed likely to end the scene. By dint of hard work he was again rallied, and the chloroform pushed until perfect insensibility was produced, and maintained for some time. On rallying from this, he soon commenced vomiting, and ejected from the stomach a quantity of apple he had eaten directly after taking the poison. After this, he began to exhibit evidence of improvement; the spasms being gradually lessened until 7 P.M. We were able to discontinue the medicine, which had been used almost without intermission for seven hours, consuming 1 lb. of chloroform. At this time a small quantity of urine was passed, the first that had escaped during his illness. And again at 9 P.M., he had another evacuation, which was reserved for subsequent analysis. This, subjected to the usual process of analysis, gave unequivocal evidence of the presence of strychnine. In regard to the agent to which we are indebted for a cure in this case, I think that while great relief from suffering was due, and also vomiting was indirectly due, to the chloroform, we should have failed utterly had not a portion of the poi-

son been ejected from the stomach, and its absorption into the general circulation prevented. The subsequent treatment of the case consisted in the use of anodynes and diuretics—the latter with the hope of hastening the elimination of the poison from the system through the renal secretion.

Yours, etc.,
L. A. HAMILTON.

CHARDON, OHIO, Feb. 17, 1867.

THE OPHTHALMOSCOPE AND CEREBRAL DISEASE.

[TO THE EDITOR OF THE MEDICAL RECORD.]

DEAR SIR—I am happy to find in the number of your valuable journal of Feb. 15, page 565 (Report of the Meeting of the Medical Society of the State of New York), a statement, which probably comes nearer the truth than the speaker intended, to wit:—That amaurotic symptoms, diagnostic of cerebral disease, depend in NO CASE, in reality, upon a plug in a defective tooth.

Familiarity with the use of the ophthalmoscope had convinced some persons of this fact before, but additional testimony is always of value.

Yours truly,
B.

NEW YORK, Feb. 20, 1867.

Medical News and Items.

PERSONAL.

RUSH MEDICAL COLLEGE.—Prof. Gunn, of the Michigan University, has been appointed to the chair rendered vacant in the Rush Medical College by the death of Prof. Brainard.

HARVARD MEDICAL SCHOOL.—Dr. James C. White, the talented junior editor of the *Boston Medical & Surgical Journal*, has retired, in order to accept an adjunct professorship of Medical Chemistry, in the Harvard Medical School.

DEATH OF DR. KELLOG, U. S. N.—DR. KELLOG died suddenly at Montevideo on the 7th instant.

DEATH OF THOMAS K. CHANDLER, U. S. NAVY.—The St. Thomas papers announce the death, on the 5th instant, of Thomas K. Chandler, Acting Passed Assistant Surgeon of the United States Navy on duty with the steamer Penobscot. The deceased was a native of New York, and was appointed to the position he occupied at the time of his death on the 9th of June, 1866, and was assigned to duty with the Penobscot. His death was caused from yellow fever, which disease has been prevalent at St. Thomas for several weeks past.—*N. Y. Herald.*

MEDICAL CONVENTION.—At the meeting of the American Medical Association, held in the city of Baltimore, May 3, 1866, the following resolution was adopted with much unanimity, and the undersigned appointed a Committee to aid in carrying it into practical effect:

Resolved, That this Association earnestly requests the Medical Colleges of the country to hold a convention for the purpose of thoroughly revising the present system of Medical College instruction, and that a Committee be appointed to aid in carrying the resolution into effect.

In fulfilling the duties enjoined on them, the undersigned respectfully and earnestly invite the Trustees and Faculty of each regular Medical College in the United States, to send representatives to a Convention to be held in the city of Cincinnati, Ohio, on Friday preceding the next Annual Meeting of the American Medical Association, namely, on the 3d day of May, 1867. We would also respectfully suggest that all delegates to such Convention be prepared to consider fully and act upon the following subjects:

First. The adoption of a more uniform and just rate of Lecture Fees by all the Colleges in this country. *Second.* The propriety of increasing the length of the Annual Lecture Term, and the number of Professorships. *Third.* The adoption of measures for securing more thorough attention on the part of the students to the more elementary branches of medical science, and a more progressive order of medical studies. *Fourth.* The practicability of requiring three Annual Courses of Lectures, instead of two, as a condition of graduation; and of making Hospital Clinical Instruction a necessary part of the Third Course. *Fifth.* The practicability of establishing and exacting some appropriate standard of preliminary education for young men proposing to enter upon the study of medicine.

Feeling confident that a free interchange of views upon these and such other topics as the Convention might deem proper, would result in the adoption of measures of great importance to the interests, honor, and usefulness of our profession, we again cordially and earnestly invite your coöperation.

N. S. DAVIS,
S. D. GROSS,
WORTHINGTON HOOKER,
M. B. WRIGHT,
GEO. C. SHATTUCK,
} Committee.

URIC ACID FROM PERUVIAN GUANO.—Dr. Lowe heats one part by weight of oil of vitriol in a porcelain dish placed on the water-bath, and adds gradually the same weight of previously dried and powdered guano, constantly stirring with a glass rod. Much carbonic and muriatic gas is evolved, which must be guarded against, the dish being kept on the bath as long as the escape of hydrochloric acid is perceptible; the mess is then diluted with twelve to fifteen times its bulk of distilled water, and after settling, decanted from the insoluble portion, and this is once or twice repeated, the liquor being filtered, and the sediment collected on the filter and washed until nearly free from sulphuric acid; after which, it is boiled in a porcelain dish with dilutic caustic soda, the solution filtered, and precipitated by the addition of a small excess of hydrochloric acid. The crystallized acid is collected on a filter when cold, washed with water, and if necessary, decolorized by heating it for a short time on the water-bath in a porcelain dish with its own weight of oil of vitriol, diluting afterwards very gradually with water, and washing on a filter.—*Druggists' Circular.*

A MEDICAL GOVERNOR.—By the election of Governor Swann, of Maryland, to the United States Senate, Dr. C. C. Cox, the Lieutenant-Governor, succeeds to the office thus vacated.

SPECTRUM ANALYSIS.—Prof. Henry Draper delivered a lecture on the evening of the 19th ult., at the Rutgers Institute, on "Spectrum Analysis," which was illustrated by images thrown on a camera, and illuminated by the magnesium light.

THE AQUATIC ANIMALS OF THE AMAZON, was the subject of an interesting lecture delivered the same evening, by Prof. Agassiz, at the Cooper Institute, under the auspices of the Association for the Advancement of Science and Art.

Death from Chloroform at Bellevue Hospital.—A death from chloroform took place recently at Bellevue Hospital on the occasion of the performance of a rhinoplastic operation by Professor Hamilton. The patient was a robust, middle-aged Irish woman, whose nose had been bitten off in an encounter with a negro. A preliminary operation had been made for the purpose of forming a flap for the new member, and everything had progressed favorably. The second operation was intended to complete the formation of the nose, but before it could be commenced, the patient expired. It seems that chloroform had been first administered by two of the hospital internes with a view of bringing the patient rapidly under the influence of an anæsthetic, and an effort was afterwards made to employ ether, but insensibility not being satisfactorily induced, chloroform was again employed with the desired result, and the anæsthesia afterwards kept up by ether. As the operator was about to commence, the patient was noticed to grow suddenly pale, the pulse ceased at the wrist, and despite every exertion to resuscitate her by means, first, of artificial respiration, then of the galvanic battery, and afterwards by artificial breathing following laryngotomy, the patient expired. The materials were chemically pure, and the usual care was taken in their administration. Death took place as the result of paralysis of the heart.

Eulogy on Prof. Joseph M. Smith.—Dr. W. C. Roberts read a very interesting and eloquent eulogy upon the late lamented Professor Joseph M. Smith, on Wednesday evening, Feb. 6, before the New York Academy of Medicine. The meeting was well attended, and the audience paid the orator the high compliment of the strictest attention.

Legalized Prostitution.—It is stated on reliable authority, that Assemblyman Jacobs's bill for the regulation of prostitution, to which we have already referred, has a fair prospect of becoming a law.

Quarantine.—The Board of Health have adopted a memorial declaring that full and unrestricted authority should be vested in the Commissioners of Quarantine to allow them to obtain a site for quarantine purposes by the power of eminent domain, if it cannot be secured by purchase. The document has been forwarded to the Legislature.

Milk consumed in New York and Vicinity.—The milk consumed in the city of New York and its immediate vicinity, is estimated at an average of three hundred thousand quarts a day.

Death of Dr. W. Brinton.—Dr. William Brinton, F.R.S., the distinguished London physician, died of uræmia on the 17th of January, aged 43 years.

St. Luke's Hospital.—Dr. Charles F. Taylor has been appointed Consulting Orthopœdic Surgeon to this institution.

Ligature of the Right Subclavian and Carotid Arteries.—Professor Joseph C. Hutchison recently ligated simultaneously, the right subclavian in the third portion, and also the right carotid, for aneurism of the arteria innominata. The operation was performed at the Brooklyn City Hospital, and the patient promises to recover. A detailed history of the case will shortly be furnished our readers by the operator.

Prevalence of Criminal Abortion.—But the worst feature of this matter is its increased and increasing prevalence. Formerly it was almost exclusively adopted to get rid of the encumbrance and shame of illicit intercourse; and by the masses of society, especially the moralist, it was considered as the natural result of such carnal indulgence; and only susceptible of control as the higher religious sentiment prevailed, influencing men to self-restraint. Of course, taking the world as we find it, there was little hope of accomplishing much towards the abatement of the evil—and it could only be held in check by operating upon the fears of men, through law. Now, however, the exceeding prevalence of the evil is found to be among an entirely different class, and the fruit of legitimate wedlock in every grade of society, high and low, but especially the former, is the prey of this destroying Moloch. There is reason to fear that in this present age, but few of either sex enter into the marital relation, without full information as to the ways and means of avoiding or destroying the legitimate results of matrimony—in the one case, whether by injections, imperfect intercourse, or the abominable French appliance, conception is prevented; while in the other, by medicinal or mechanical means, they destroy the fruit of conception; for they are often sufficiently instructed to be quite independent of outside helps. Among married persons, so extensive has this practice become, that people of high repute not only commit this crime, but do not even shun to speak boastingly among their intimates, of the deed and the means of accomplishing it. Is there a physician here present, whose experience does not fully confirm the statement? Gracious Heavens! and has it come to this, that in an age of advanced Christianity, with the advantage and refinement which education is supposed to bring, woman, the dearest, best, and purest of God's creation, can descend to this lowest level, and become a murderess, and that too of her own offspring!—D. M. Stewart, *Detroit Rev. Med. and Surgery.*

Production of Sexes at Will.—Dr. Thos. Liscomb (Nashville *Journal of Medicine and Surgery*), with reference to M. Thuny's theory of the production of sexes at will, says: "We believe that the Creator, in infinite wisdom and with that beneficence to the creature man that characterizes all of his dealings with him, has reserved this secret to himself; veiling it in mystery so profound as to cause it to remain for ever hidden from the researches of man. If so, it is doubtless best that it should so remain. Discover this secret to man, and what might he not attempt? He might, in the exercise of his limited capacity, conclude that first one and then another animal was useless in the world; and then, with an amount of zeal worthy of a better cause, commence his work of destruction of that particular species, by so regulating the intercourse of the sexes as to prevent any female offspring being begotten, thus severing link after link in the great chain of animated nature. And the wickedness of man might not stop here, but a serious and grave interference with the propagation of his own species might be attempted and accomplished; as we all know that there is a foolish and wide-spread prejudice with many parents against having daughters born to them; an overweening anxiety for boys, as foolish as it is wicked, as if the great God who regulates these things was not the best judge of what was best for us, and best for the world. And as the unerring word of inspiration has declared that man is desperately wicked, and our own observation and experience abundantly attest the truth of the declaration, what other great wickedness might he not attempt?"

Prof. Rosas of Vienna.—In a lecture published in the *Buffalo Medical and Surgical Journal*, relating to medical affairs abroad, among other interesting facts, it is noted that "Professor Rosas" has an eye clinic in the General Hospital in Vienna. If we are not greatly in error, Professor Rosas has been dead quite a number of years. Professors Arlt, Stellwag, and Jaeger are the living teachers of ophthalmology in Vienna.

Original Communications.

AN OPERATION FOR ABSCESS OF THE APPENDIX VERMIFORMIS CÆCI.

By WILLARD PARKER, M.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

FAMILIAR as we are with the diseases to which the alimentary canal is liable, there is one part of it—the appendix vermiformis—the pathology of which is, to a great extent, involved in obscurity. In the ancient literature of the profession we find nothing in regard to it; in fact, we have no reason to suppose that attention was ever directed to it as a part which might be the seat of special disease. And this neglect is not to be wondered at, when we reflect that, by its position, the appendix vermiformis is insignificant; and, by its anatomical similitude with the rest of the intestinal tube, it is impossible for disease affecting it to remain for more than a limited period, local. In many cases, general symptoms too rapidly intervene to allow an exact diagnosis to be made out; and, frequently, it is only at the autopsy that we become acquainted with the precise nature of the disease which has terminated the life of the patient.

During the present century, however, the zeal of the profession, which has been at work, uprooting the hidden things of the past, has not suffered investigation into the obscure physiology and pathology of the appendix, to remain wholly idle. Various papers, by English, French, and German authors, have appeared;* besides occasional cases, which from time to time have found their way into the medical journals. But although much has already been done, much still remains to be accomplished, before the obscurity surrounding this subject will have been entirely removed.

There are, however, three diseases of the appendix vermiformis, which have been classified from post-mortem appearances:

1. Gangrene.
2. Perforating Ulcer.
3. Abscess.

To these, Rokitanski adds a catarrhal affection of the appendix, which may be only the commencement of a graver condition, or which may exist by itself as a distinct disease. By some, these diseases have all been grouped together under the general name, Typhlitis. † They all have the same origin, viz. the impaction of calculous masses in the calibre of the tube, or the presence of foreign substances, such as the seed of fruit, shot, etc. These may become causes of disease, either by obstructing the circulation of the part, or by their presence, simply, they may give rise to irritation and inflammation.

Gangrene, and perforating ulcers of the appendix vermiformis, usually occur in male children, and prove fatal in from two to five or six days. No certain diagnosis can be made out. Violent symptoms of general peritonitis set in, and it is rare that medical interference is of any avail.

Abscess of the appendix, on the contrary, generally attacks those past adult age; is slower in its progress, and presents symptoms more easy to recognise. An attack is ushered in by pain in the bowels, suddenly coming on; loss of appetite; nausea, vomiting, and perhaps some febrile action. In a short time the pain circumscribes itself in the right iliac region; nausea and vomiting continue; the bowels are constipated; skin dry and feverish; pulse inflammatory; tongue thickly coated; abdomen somewhat tumid and resonant on percussion—also sympathetic tenderness over its whole extent. After the lapse of a few days, a small circumscribed tumor may be detected in the neighborhood of the right iliac fossa.

All of the symptoms may not be present in every case, and some of them are common to other diseases. Uncertainty may exist with regard to the diagnosis. It may be difficult to determine whether a case is internal hernia, abscess of the appendix, or intussusception. The greatest diagnostic mark to be remembered, is this: In the above-named diseases (internal hernia and intussusception) there is insuperable obstruction in the bowels, while in abscess of the appendix vermiformis there is no such obstruction. The administration of a cathartic, then, will clear up all obscurity. And it is to be remembered, also, that in abscess of the appendix, the action of a cathartic produces, at first, marked relief of all the symptoms; but this relief is only temporary. Accordingly, then, as a cathartic acts efficiently or not at all, we are able, by exclusion, to arrive at a tolerably certain diagnosis; the more so, as we are aided by the symptoms already enumerated, the pain and circumscribed tenderness over the iliac fossa.

The prognosis is bad. The end is generally death. Dr. Lewis reports* forty-seven cases of diseased appendix, all of which terminated fatally. Death occurs in this way: When the pus has accumulated in sufficient quantity, it forces its way into the cavity of the peritoneum, a violent peritonitis is induced, and death rapidly ensues. All, however, who have abscess of the appendix vermiformis, do not die. In a few cases, adhesions, strong enough to keep the contained pus from invading the peritoneal cavity, are created around the abscess, and the pus finds an exit by ulceration, either into some portion of intestine, generally the cæcum, or through the abdominal wall.

The following cases are illustrative:—

In 1843, I was called in consultation to visit Dr. T., of Brooklyn. He had been confined to bed for some weeks, suffering from pain in the bowels, constipation, disturbance of system, fever, tenderness in right inguinal region, etc. On examination, I found a swelling in the neighborhood of the iliac fossa, in which questionable fluctuation existed. An opening of exploration was made, which justified a free incision. I accordingly cut down into, and excavated the contents of the abscess; with the pus, a little concretion, the size of a raisin-seed, came out. In a short time the patient recovered, and is living now, in good health.

I saw Mr. D., æt. forty-five, a strong, healthy farmer, on the 20th of May, 1865. He had been sick for six days with pain in the bowels, tenderness over right iliac fossa, etc. He was lying on his back, his legs drawn up; his bowels had been freely moved. I prescribed a blister, opium, and nourishment. I next saw

* Husson and Dance, "Sur quelques Engorgements Inflammatoires qui se developpent dans la Fosse Iliaque Droite. Repertoire Général. Tome iv., 1827."

"Des Abcès de la Fosse Iliaque Droit. Leçons Orales de Dupuytren. Tome iii., 1833."

By these observers, abscesses of the right iliac fossa, and the symptoms accompanying them, were described, but they failed to perceive the connexion which these bore to inflammations originating in the appendix vermiformis. They thought that they were all "primarily inflammations of the cellular tissue in the right iliac fossa, which may terminate in resolution, suppuration, or universal peritonitis."

It was reserved for Dr. Burne, "Medico-Chirurgical Transactions," vols. xx. and xxii., to establish the true relations of these abscesses, and trace them back from effect to cause.

† Purchelt, the first German physician who gave particular attention to these conditions, proposed the name perityphlitis.

* New York Journal of Medicine. November, 1856.

him on the 17th of June. He was weak and emaciated from the severity and continuance of the attack. A tumor had appeared over the region of tenderness, which two days previously had grown considerably smaller, and at the same time a liquid, supposed to be purulent, discharge had taken place from the bowels. The tumor was soft to the touch, and presented a point where pus was near the surface: this I laid open with a bistoury, and considerable purulent matter, with gas, made its escape. Following this was improvement and perfect recovery. In this case the abscess had broken, not only through into the intestine, as was shown by the reduction in the size of the tumor, simultaneously with a discharge from the bowels, but ulceration was already commencing to form a track for the escape of the pus through the abdominal walls.

C. J. O., æt. twenty-one, robust, had suffered for two years from dyspepsia and chronic diarrhœa. He stated that, on the 10th of June, 1865, he was attacked with peritonitis, the pain being intensified over the right iliac fossa. On the 16th, the general inflammation having abated, he noticed a swelling, hard to the touch, and very painful, above the right groin. This tumor gradually enlarged, until the 20th of August, when I first saw him. It presented a circumscribed appearance, had a doughy feel, and sometimes crepitated as if it contained gas. Leeches were applied and poultices; the bowels were made to act, and he had got so far well as to be able to attend to his business, though the tumor and hardness had never entirely disappeared; when, in the latter part of November, he had a recurrence of his difficulty. On the 4th of December I made an incision, through which some pus and a small calculus made their escape. On examination the latter was found to consist of uric acid, biliary matter, and some débris of muscular food. On the 16th of January, the tumor in the meantime having disappeared, leaving only an indurated hardness, the patient was again attacked with violent pain, vomiting, etc., as at the first. On the 17th, some enlargement was noticed, and on the 20th (it having attained the size of a man's fist, and fluctuation being discovered), it was opened, and pus copiously discharged therefrom. In a short time the flow of pus had ceased, the parts resuming very nearly their normal condition. He soon returned to his home in Connecticut, where he now is. In a letter dated April 6, 1866, he says that his general health is poor, being troubled with weak bowels and vomiting, but his side has given him no inconvenience since it was last opened.

A fact, which bears somewhat upon the prognosis, is discovered in looking at the anatomical position of the appendix. Its origin is generally from the inferior, posterior, and inner side of the cæcum, and it may be of varying size, and occupy various positions. It may depend into the pelvis and lie over the iliac fossa: it may lie curled up behind the cæcum, on the outer edge of the psoas magnus, upon the fascia iliaca: or it may lie encircling the cæcum and extend up along the colon for four or five inches. By remembering the last position our diagnosis will be aided, rather than the prognosis, for we will be prepared to find the tenderness and circumscribed swelling at a higher point upon the abdomen, than the region over the iliac fossa. When the appendix lies behind the cæcum upon the fascia iliaca, its inflammation and abscess become of less importance, for the peritoneum in this case is not involved, and the direction of the abscess is towards the outer margin of the quadratus lumborum, where the parietes offer but little resistance. These last positions of the appendix, however, are rare, and they are only mentioned as being among the possibilities.

The duration is variable, and depends upon the absence or presence of adhesions. In the first case the patient dies in from two to four or five days. In the second, death cannot occur so long as the adhesions keep the peritoneal cavity intact. These are in danger of being broken as long as the formation of pus is on the increase; that is, until its maximum is reached, which, in all probability, will be by the twelfth day. The adhesions, if they break at all, will have broken by this day, so that we may conclude, if the patient survives the fifth day, Nature is putting her seal of safety upon the case. Death may occur after the twelfth day, but the chances are greatly diminished.

Of the general treatment I have little to say. Absolute rest on the back, opium, and such nourishment as will maintain the plastic integrity of the blood, will be sufficiently indicated to every practitioner.

The matter of local treatment, however, has attracted my attention for many years. These questions presented themselves: Are the efforts of nature exerted in behalf of a cure, and if so, in what way? Observation indicates the reply, and experience verifies its truth. Nature does labor in behalf of life, in two ways: 1st, by means of the wall of false membrane, which she builds up around the abscess; and 2d, by the ulceration, which gives an external vent to the escape of its contents. This being settled, it became a question whether surgery might be able to render assistance to Nature in this work; and if so, at what period would interference best come in?

In what has gone before, it would seem that in some cases no adhesions are formed, and general peritonitis quickly carries the patient to the grave. It is obvious, in these cases, that surgery can be of no avail.

It has likewise been seen that many cases are prolonged beyond the fifth day. In these we have evidence of an adhesive inflammation, and we know that the next step in the progress of the case will be ulceration. The only danger now to be feared is, that before ulceration can fully accomplish its purposes, the pressure of the accumulating pus will break through the recently formed adhesions, and the event will be the same as if no adhesive inflammation had taken place. Just here, if at all, the office of the surgeon becomes necessary; for by making a free incision down to the point where pus is collected, we have a method by which we may supersede nature in its slow process of ulceration. By this means, the pus will escape as soon as it is formed; consequently there will be no pressure upon the recent adhesions, and even though weak, they will be strong enough to answer all the purposes for which they were created. The time for making the incision is a matter of great importance. To be successful, it is necessary that it should be made neither too early nor too late—not before adhesions are fully formed, nor after a short period before the maximum formation of pus has been reached; that is, the incision should be made after the fifth day, and before the twelfth.

Reasoning thus, I had convinced myself of the practicability of an operation, in cases of abscess of the appendix vermiformis. Of its safety there could be no doubt, for there was no danger in the division of those structures through which the incision would pass. That it was perfectly justifiable, I had no doubt, for, taking into consideration the two possibilities of any case, I could find no reason why the operation should not be performed. The first of these, was where the diagnosis had been clearly made out. This has been sufficiently dwelt upon in the foregoing paragraphs. The second, was in those cases in which there was doubt as to the diagnosis. If no abscess had already formed, in case one should be in process of formation, an external

opening would tend to make it point in a safe direction. And even if no abscess should form, a free incision would relieve tension, thus adding to the comfort of the patient, and in no way prejudicing his safety. One other question remained. Would the operation be successful in bringing about a cure? Judging from the result of the three cases reported above, an affirmative answer seemed certain; for these recovered, because in each one nature had provided for an external discharge of the contents of the abscess, and what nature had provided for in these three, an operation would provide for in all cases. These theories received final confirmation in the result of the case, the report of which follows:

J. D., æt. 40, strong, of full habit, was attacked with pain in the bowels at half-past four o'clock in the morning of Friday, January 12, 1866. He has been more or less subject to severe attacks in the bowels for some years. The night preceding the present attack, he had been out with friends and had eaten a late supper. At five A.M. he vomited, and felt some pain in the right iliac fossa. At eight, he took coffee and toast, after which he went down town. During the day he had no appetite, and took no food until evening, when he ate a little cold chicken. There was no movement from the bowels during the day. In the night he had nausea. On the 13th he arose early, having passed a restless night. After breakfast he took two blue-pills. During the day he suffered from pain in the right side, which was relieved by bending over to that side. On the 14th, there being as yet no movement from the bowels, he took a glass of Saratoga Empire water. Pain, restlessness, and nausea still continued. Mustard was applied over the affected side. This evening he had an inefficient movement from the bowels. On the 15th, the above symptoms increased in severity, continued, and in addition he was troubled with eructations. In the evening his family physician, Dr. Sabine, saw him, and ordered opium and a blister to the affected side, also leeches. On the 16th, I saw the patient in consultation with Dr. S. We found him with a thickly coated tongue; no appetite; nausea, and a constipated state of the bowels; pulse inflammatory, ranging over 100; skin dry and feverish; abdomen tumid and resonant on percussion; pain in the whole abdomen, but more decided in the right iliac fossa. Over this was a circumscribed tenderness, the boundaries of which could easily be marked out by the fingers. Micturition painful; pain also extended down the right thigh, and to the right testicle, which was drawn up. He was lying with his right thigh flexed on the pelvis, which position gave him some relief.

The case was diagnosed as probably abscess of the appendix vermiformis. To render it certain, however, that there was no internal hernia, intussusception, or impaction of fæces, and to clear up the diagnosis, we ordered calomel, gr. xv., and opium, gr. iij., to be given in three doses. On the morning of the 17th, ol. ricini ℥j, with tr. opii gtt. xx., were administered, and operated freely, a large quantity of scybalous fæces coming away. The immediate effect was an amelioration of all the symptoms. The pulse became soft, and fell to 80; skin moist; tongue less coated; some return of appetite; abdomen less tumid, and the pain became definitely circumscribed in the right iliac fossa. On the 19th, his symptoms indicated a return of his former condition. During this day he was kept under the influence of opium, and on the 20th, finding his symptoms more unfavorable, his exact condition was explained to him and the operation proposed. It was, with his consent, decided that if on the next day there should be no improvement, it should be performed. On the 21st, there being no change for the better, but if anything for the worse, and it now being the ninth day of the attack, it was decided to operate as soon as practicable. An injection of catnip tea was given, to relieve the bowels of wind, and at half-past two P.M., assisted by Drs. Sabine, Sands, Thomas Sabine, and my pupil, Mr. Wynkoop, I commenced the operation.

An incision six inches in length was made through the integument, commencing above, and about one inch from, the anterior superior spinous process of the ilium, running towards the symphysis pubis. About one inch of the incision was above an imaginary line drawn from one ant. sup. spin. proc. to the other, and five inches below. The incision was continued carefully down, and all the structures found to be healthy, until the fascia transversalis was reached, which was found to be thickened. This was divided over a director, and right beneath a tumor was felt, which was about two inches long and an inch and a half in width. An exploring needle was introduced, when immediately there gushed up some thick, bad-smelling pus. The sac was now freely opened, and about four ounces of pus, in which there may have been a little fæces, discharged. A tent was introduced into the cavity, and the wound left to close up by granulations. The patient rallied well, after the operation, and passed a good night. The next morning he was in a quiet condition; pulse 84, soft; tongue more moist; abdomen soft; but little fever; wind escaping freely from the bowels; wound discharging healthily. The after treatment consisted entirely of rest, opium, and nourishment. Perfect recovery took place in three weeks, and at the date of writing (December, 1866) he is enjoying perfect health.

POLITZER'S METHOD OF TREATMENT

WITH TWO CASES OF ACUTE AURAL CATARRH.

By HENRY L. SHAW, M.D.,

SURGEON TO THE EYE AND EAR INFIRMARY, BOSTON.

The treatment of diseases of the ear by the apparatus of Politzer, in connexion with Roosa's modification of Buttle's inhaler, although much practised, has not received the attention, from the profession generally, to which it is entitled. We are indebted to our friend Dr. Roosa for having first called our attention to the good results following this method of treatment, which have been fully confirmed by our own experience.

The treatment can hardly be said to take the place of the eustachian catheter; yet, in many instances, it will be found an efficient substitute. No objections of importance can be urged against its use. For in its operation it is harmless and unattended with pain; the sensation produced by the introduction of a foreign body into the nostril, being the only unpleasant sensation accompanying its use. The epistaxis which it sometimes causes, is a trifling matter, and is not unfrequently due to the faulty manipulation of the operator. In persons of a hæmorrhagic diathesis, this is liable to take place, even when the utmost care is used. Rupture of the membrana tympani is mentioned as one of the accidents attributable to its use. We can conceive that such an accident might occur. But by regulating the force by which the bag is compressed, we believe it may almost invariably, if not always, be avoided. In a large number of cases treated by us, it has never occurred. As is well known, the amount of force necessary to inflate the ear, varies in different patients. This is also the case with the same patient at different times. Sometimes a very forcible compression of the bag will be required; and perhaps it may be

necessary to repeat the operation several times before we shall be able to perceive with the otoscope the audible click which notes the entrance of air into the tympanic cavity. The patient may be deceived with reference to the click; and until he becomes accustomed to the sensation, it is well to confirm his assertion in the manner above described. Should the click not be heard, we think it is safe to conclude that the tube is closed. Cases are not unfrequently seen where it is impossible to inflate the tympanum early in the treatment. This impossibility often arises from the inflammation and swelling of the mucous membrane adjacent to the mouths of the eustachian tubes. The diagnosis of this trouble is now very much facilitated by the rhinoscope; and under the persistent use of local remedies the tubes can oftentimes be rendered inflatable.

We have not relied upon the use of the bag alone; the inhaler has been used in connexion, in nearly all instances. The sponge has been moistened with Tr. of iodine, a weak solution of nitrate of silver, or any agent which seemed applicable to the case. The introduction of air alone may be of great service, and occasionally, it is sufficient for the cure. Yet it will be found in many instances, that the cure will be hastened by the use of some medicated vapor. That the vapor passes into the tympanum we have demonstrated in the following manner, in the cases of patients with internal otitis, and of those having perforations of the membrana tympani. The external auditory passage having been thoroughly cleansed, a piece of soft paper or cotton soaked with starch, is inserted in the bottom. Iodized air is then forced through the inhaler, when the characteristic iodide of starch will be found.

The following cases are typical of a class very commonly met with. In each instance cited, the improvement of the hearing was rapid and permanent. No more so, however, than is often the case.

March 27.—Miss D. T——, aged 24; strumous temperament. Fair health. During childhood had enlarged tonsils, which were removed. Three years ago, had a slight discharge from the ears, which lasted but a few days. Since that time, has had several attacks of slight deafness of short duration. Present trouble came on suddenly seven weeks ago. Now hears conversation, if very loud, at two feet. Hearing point with watch, left ear, half an inch. External auditory passage and membrana tympani normal. Eustachian tube not inflatable, although she says she herself has been able, until quite recently, to force air in by closing the mouth and nostrils. Right ear, hearing point with watch in contact. Eustachian tube not inflatable. Auditory passage normal. Handle of malleus very prominent. Its connexion with the membrana tympani unusually vascular. Mucous membrane of throat inflamed, but not swollen. Complains of dryness of the fauces.

Treatment: Solution of nitrate of silver, ten grains to the ounce of water, was applied to the tonsils and about the mouths of the eustachian tube. ℞ Tr. iodini, potass. iod., *ā ā.* ʒ ii., Aq. pur. Oii. M. As a gargle four times daily.

April 2.—Solution of nitrate of silver applied to throat. Gargle continued.

April 7.—Throat is better; says her mother's voice sounds more natural. Hearing point with watch as at first visit. Sol. of silver applied to throat. Gargle continued. Ordered Tr. ferri chlor.

April 17.—Within past few days, has had several marked cracks in both ears, followed by improved hearing, lasting for several hours; in one instance nearly all day. Politzer's bag, with the inhaler containing iodine, was used for the first time. The result was an improvement of six in. in the right ear, and four in the left. Conversational hearing power but slightly improved. Treatment continued.

May 2.—The bag has been used several times since last record. There is a gradual improvement. Throat touched. Treatment continued.

May 10.—Hears ordinary conversation at fifteen feet. The watch is heard at twenty-four in. right ear; twenty-one in. left. Is able to perform duties which her defective hearing unfitted her for before. A single vessel noticed at the connexion of the malleus with the membrana tympani. The former is less prominent. Eustachian tubes normal. She was heard from eight months afterwards, and had no return of the trouble.

November 22.—Mr. T. O. X——, aged 30; sanguineous temperament. Six weeks ago, after exposure, was taken with a severe coryza, which in a few days improved, leaving him deaf. The function of the olfactory nerves is seriously affected; is unable to distinguish the most pungent odor. Taste is also affected, but in a less degree. Hearing point with watch, left ear, contact; right, not heard. Conversation, to be understood, has to be very loud and distinct, and within a foot of the ears. He is then aided by watching the motions of the lips. External auditory passages normal. Membrana tympani, right, dull; left, normal. Several large blood-vessels at the connexion with the malleus; mucous membrane of throat and nares inflamed; that portion over the vertebral column, granular. The marked character of the symptoms, together with the impairment of the olfactory and gustatory nerves, led me to ask the attention of my colleagues before adopting any treatment. Iodized air was inflated with the following result: conversation in an ordinary tone, addressed to others, he heard quite well. Point with watch one and a half inches, right ear; left, not noted. Ordered tr. of iodine gargle as in the previous case.

Dec. 1.—Since last record, iodine air has been used several times. Conversational hearing power improved. Has been able to hear the watch at two and a half inches most of the time. Tympanum inflated, and throat touched with the solution of silver. Treatment continued.

Dec. 6.—After inflation, watch is heard at four inches. Throat touched with tr. of iodine. Treatment continued.

Dec. 31.—Converses with but little difficulty. Hears watch at eight inches, both ears. Throat improved. Ordered gargle of red pepper, vinegar, sugar, and water, as a substitute for iodine gargle.

Jan. 25.—Seen twice a week since last report. Hears ordinary conversation at twenty feet; point with watch, twenty-five inches, being about the normal average.

Feb. 15.—Considers his hearing as acute as ever. He is still under treatment for his other troubles, which have improved but slightly.

41 Essex Street, Boston.

Chemists' Certificates.—The *Boston Medical and Surgical Journal*, in alluding to the practice of granting chemical certificates for different injurious articles of commerce, says: It is no defence for the chemist, in this and other instances which might be mentioned, where certificates are given for such or equally injudicious purposes, to urge that he is not accountable for the use which is subsequently made of them. Such a plea of irresponsibility will not be accepted by those who respect chemistry and who fully appreciate the character of such pseudo-scientific labors, and of the parties who use them for such unworthy purposes.

LARYNGOSCOPY.

By J. SOLIS COHEN, M.D.,
OF PHILADELPHIA.

No. VII.

HISTOLOGY OF THE LARYNX.

According to the researches of Luschka, whose *Anatomie des Menschen* is the most elaborate and instructive on this subject which the writer has consulted, we learn that the cartilages of the larynx are composed of true cartilage structure—fibro-cartilage and reticular cartilage. The thyroid, cricoid, and the greater portion of the arytenoid cartilages, are formed of ordinary cartilage, bluish white in color. This form has considerable disposition during the course of time to undergo pathological degeneration. It undergoes earliest the fibrous degeneration, by which it becomes fragile, assumes a yellow color, or becomes spotted with yellow, and grates under the knife. In the so-called granular degeneration it assumes a turbid color, sometimes yellowish, sometimes the color of asbestos. The intercellular substance is filled more or less with larger and smaller dark molecules, and contains distributed through it, isolated larger granular bodies. Sometimes the degeneration is into porous osseous substance, richly supplied with adipose matter, and this occurs so frequently in mature age that R. Columbus (*J. B. Morgagni, Adversaria Anat.* 1, 23) does not hesitate to enumerate the larynx with the osseous system. The ossification occurs most frequently in the cricoid and thyroid cartilages, sometimes occurring earlier in one, at other times in the other. Ségond says that the muscular process is always the starting-point of the ossification; and that next to the influence of age, the amount of exercise influences its degeneration. And he contends that this occurs earlier and in greater extent, among professional vocalists, than among individuals who do not make extraordinary use of their voices.

Less frequently than ossification, we meet with infiltration of carbonate of lime, which is also said to occur in the capsules of the cartilage, as well as its hyaline substance.

The epiglottis, the cartilages of Santorini, of Wrisberg, the sesamoid cartilages, the vocal processes and points of the arytenoids, the colliculus and vocal processes of the thyroid cartilage, are composed of yellow or reticular cartilage. These are liable to calcification rather than ossification.

The thyroid cartilage is ordinarily described as composed of two plates, alæ, or wings, which are joined at the centre. This is not sufficiently exact. It was first pointed out by Rambaud, and subsequently by J. A. Cavasse, Halberstma (Luschka), *et al.*, that there is an intermediate or central cartilage uniting the two wings —the lamina intermedia. This has much the form of an inverted wine-glass with flaring edges, or the large extremity of a trumpet; but occasionally it is rhomboidal in shape. It can be recognised in all ages and in both sexes, and can be readily separated in the unossified larynx after the perichondrium has been fully removed, which can be best done in those which have been immersed for some time in alcohol. A transverse or vertical section will show its existence, and it can be isolated by maceration in a dilute solution of potassa. It is composed of a hyaline cartilage structure, and by its more greyish color can be distinguished from the milky white of the alæ proper. The cartilage of this intermediate portion of the thyroid on its inner surface, receives the anterior vocal processes, to which the true vocal cords are attached. It has been shown by Gerhardt to be composed of reticular cartilage, but it departs from the usual construction of reticular cartilage, inasmuch as instead of the usual thickly matted small, dark, short elastic fibre arrangement, here, paler fibrils, sometimes plaited in bands, cross each other, sometimes horizontally, sometimes curvilinearly, forming interspaces in which large cartilage cells are here and there distributed. This fibrous cartilaginous structure has been found unchanged by Luschka, even when the lamina intermedia had become completely ossified, which circumstance would seem to show that it may maintain some important physiological relation to the true vocal cords.

We have spoken of the yellow color of the vocal processes of the arytenoids. It is demonstrable by the microscope, as was first pointed out by Rheiner, that through the fibrous basement structure of their reticular cartilage, these processes are actually continuous with the fibro-elastic element of the true vocal cords.

The sesamoid cartilages first discovered by Luschka, are only occasionally present. They have been observed in various degrees of development in both sexes, at all ages, and in both feebly and strongly built individuals.

The vocal cords are duplicatures of the elastic vocal membrane of the larynx; and their remarkable susceptibility of vibration is due to a peculiar fibrous band which forms their basement structure. These cords at their extremities are reinforced with reticular cartilage, by which their vibration is secured, and their ossification prevented. Their anterior and posterior extremities are so thoroughly connected with the anterior and posterior vocal processes, that their fibrous structure is inextricably blended into the felt-like elastic element of the vocal cords. In addition to this a large proportion of the fibres of the thyro-arytenoid muscle is so intimately bound up into this duplicature of elastic vocal membrane, and so incorporated into its structure, that it actually forms the largest moiety of the body of the cord.

The question has been started as to the existence of points of difference between the larynx of the negro and that of the Caucasian. Dr. Gibb, calling attention to this subject before the Medical Society of London (see *London Lancet*, June, 1864), after alluding to the greater constancy and size of the cartilages of Wrisberg, in the negro, remarked that also in the negro "the vocal cords, in place of being flat and horizontal as in the white man, were more or less oblique from within outwards, their free border being elevated at a higher angle than their attachment, thus giving them a shelving or slanting direction outwards; the ventricles taking a direction downwards and outwards, so that any small body, such as a bead, placed upon the slanting vocal cord, would roll into the ventricle; while in the white man the ventricle is situated external to, but immediately above the plane of the true vocal cords." The writer has had but a single opportunity to make the post-mortem examination of the larynx of a negro (he means a *black* man, not a mulatto), and the appearances described by Dr. Gibb were not present,—he has in his possession the specimen with a little piece of the black skin of the neck attached; and in a number of examinations made in the dissecting room of the Jefferson Medical College of Philadelphia, by Dr. Taylor, one of the demonstrators, no difference of this kind could be detected. In several laryngoscopic examinations of mulattoes, he could not detect this difference. It may be that his own observations chanced to be upon exceptional cases, or it may be that those of the gentleman quoted were exceptional. At any rate, he is convinced that the difference between the vocal

cords of the negro and Caucasian, if it does exist, is not constant.

There are found in the reticular cartilage of the epiglottis, irregular pits or notches containing follicular and racemose glands. This inlaying with glandular structure gives it a great disposition to ulceration, which, when it occurs, usually results in ulcers irregularly serrated in outline.

The bulging belly of the epiglottis is due in part to an increased thickness of cartilage, but in a greater measure to an accumulation of glandular and adipose tissue.

The perichondrium of the cartilages of the larynx is composed of thick areolar tissue, interspersed with a few irregular elastic fibres. It contains a tolerably rich network of blood-vessels. But few nerves can be traced in it, and, according to Luschka, only as primitive fibres. According to J. Engles, who has minutely investigated the structure of this perichondrium, that of the epiglottis is most richly supplied with nerves, and upon both its surfaces.

PHYSIOLOGY OF THE LARYNX—AND OF VOICE.

The larynx belongs to that class of musical instruments in which the sounds are produced by the vibrations of reeds and tongues. There are instruments with metallic reeds, which are tense in themselves, and thus are readily thrown into vibration by the passage of a current of air; and there are others with membranous tongues (caoutchouc, etc.) which are rendered tense by stretching.

The jewsharp is an instance of a musical instrument with a metallic tongue. In some instruments, as the accordeon and its class, the reed is attached by one border, and the air compressed in its passage into a narrow column, rushes past it on three sides; while in another class, as the organ-pipe, etc., the reed covers a portion of the opening at one end of the instrument. In the class of which the accordeon is the type, the tone is produced solely by the vibration of the tongue started by the concussion of a column of air, and it will vary in character with the length and elasticity of the reed. In the class of which the organ-pipe is the type, the pitch is dependent, in addition, upon the length of the tube, and the coincident vibration of the reed, and of the air within the tube.

The larynx, therefore, may be described as a reed instrument, with two parallel membranous tongues—the true vocal cords; the instrument terminating in a forked exit tube—the mouth and the nares; while for the production of the necessary current and its conveyance into the instrument, we have the lungs as the bellows, and the bronchial tubes and the trachea as the conduits.

In order that sound may be produced, it is necessary that the lips of the glottis should be parallel and closely approximated at right angles to the axis of the tube, so that only a narrow fissure remains between them; and then the air driven against these lips of the glottis during expiration, sets them in vibration as it rushes between them, and is itself also set in vibration, just as occurs when sound is produced in the organ-pipe.

The mechanism of the vocal apparatus has been imitated by Mr. Willets, who constructed an artificial larynx by stretching a piece of thin gutta-percha around one end of a tube, allowing a portion of the rubber to extend beyond the tube; and then stretching still further the free portion of the rubber between two fixed points or projections, so as to produce a narrow elliptical fissure. Then, by blowing into the free portion of the tube a sonorous sound is produced, the pitch of which can be rendered higher by stretching the rubber so as to increase the tension and narrow the fissure; while the free lips of the rubber will be seen to vibrate during the production of the sound.

A strong current of air forced through the excised larynx of a recent subject will produce the vocal tones if the arytenoids are tied together, and the vocal cords forcibly stretched lengthwise; and the intensity and pitch of the vocal tone will vary with the degree of tension and force of the blast.

That the true vocal cords alone are concerned in the production of sound is proved by repeating the experiment of Magendie, of cutting away the epiglottis, the false vocal cords, and the arytenoid cartilages above the points of attachment of the true vocal cords, which can be done without destroying the power of producing vocal tone as long as the true vocal cords are entire, and kept tense so as to narrow sufficiently the chink of the glottis; and the same result is seen in disease, where, by cicatrization or ulceration, the epiglottis and false vocal cords have been destroyed or their functions impaired, as can now be demonstrated during life by the aid of the laryngoscope.

For the production of voice several conditions are necessary.

In the first place, the true vocal cords must approach each other and be parallel so as to cross the current of air horizontally; in ordinary respiration their edges are inclined from each other;—and secondly, the fissure between them must not exceed about a line in breadth. This opening concerns the ligamentous rima, or vocal glottis; the cartilaginous rima must remain completely closed; if the ligamentous rima were completely closed also, there would be no passage for the escape of the respiratory current, and, of course, there could be no production of sound. If the cartilaginous glottis remain open, and the vocal glottis be properly fissured, the air will rush through behind, and there will be no vocal sound. If, however, the vocal glottis be properly fissured, and the anterior portion of the cartilaginous rima closed at the points of attachment of the vocal cords, though it may be open again behind, we will have vocal tone of the same pitch as if it were closed behind also, though at the same time the two will be muffled on account of the escape of a portion of the expiratory current through the cartilaginous glottis. These conditions are occasionally beautifully demonstrated in various varieties of paralysis of the muscular apparatus of the vocal cords.

Then the escaping current of air must strike the glottis with a certain amount of force. If this is prevented by a fistule, or an artificial opening below the position of the true vocal cords, there will be no voice as long as it is allowed to remain open, because the air will escape before it can be propelled against the vocal cords; but as soon as it is closed by the finger, or by the valvular arrangement of a tracheotomy tube arranged for speaking, the voice can be produced. The amount of force with which the vocal cords are struck, can be very well appreciated in an individual with such a fistule below the level of the cords, by placing the finger upon the opening while the patient is speaking, when some of the air will escape at the sides of the finger with a peculiar forcible rush. If, however, this fistule exist above the position of the true vocal cords so that no portion of the air escapes until after it has set them in vibration, the vocal tone will be produced.

Then again, if the chink of the glottis be properly fissured, simple expiration will not accomplish tone; the air must be propelled as it were with some amount of force against the glottis, meeting with a certain resistance to its passage through.

A certain amount of tension must be maintained in

the cords, and according to the increase of tension will be the rise in pitch. If the cords are relaxed, tone can be produced only when the length of the glottis is very much shortened.

For the production of a clear, sonorous tone, there must be no impediment to the vibration of the true vocal cords; and to the inserviance of this purpose the ventricles of the larynx seem adapted, as they secure a space above the cords for their free vibration.

During the production of a proper healthy note, the cords are not alone tense by elongation—they seem stretched in width; at any rate their transverse extent is more prominent to the eye, and they assume a somewhat vaulted form, as though the escaping current of air pressed upwards their central portions. Any pathological alteration which interferes with the free movement of the cords, or which, by affecting their structure, compromises their integrity of function, their elasticity and vibratility, will produce an alteration in the character of the vocal tone.

Injury or division of the laryngeal nerves supplying the muscular apparatus, will produce alteration and destruction of voice.

The alterations in the position and tension of the vocal cords are the principal agents in the alteration of the tone, and are accomplished as follows:—

They are separated by the action of the posterior crico-arytenoid muscles; they are brought in contact by the action of the transverse and oblique fibres of the arytenoid muscles; they are rendered tense, and lengthened by the action of the crico-thyroid muscles; they are stretched transversely and shortened by the action of the thyro-arytenoid muscles; they are slackened and shortened by the action of the lateral crico-arytenoid muscles. These movements can be verified by galvanism upon the recent larynx.

During vocalization we see the true vocal cords vibrate in their entire length; that is, from one vocal process to the other; and we know from anatomical arrangement and subjective sensations, that the thyro-arytenoid muscles vibrate with them, as also the general elastic membrane of the larynx; while in deep, sonorous resonant tones, the trachea and sometimes the entire respiratory apparatus vibrate also. This vibration of trachea, etc., is probably due to the action of the glottis impeding the escape of the strong current of air which reverberates or reacts upon these structures; for it is not likely that these parts have anything to do in the modification of sound.

There are a number of agents which assist in the modification of sound. Thus, drawing the larynx down upon the sternum, by the action of the sterno-thyroid muscles, will deepen the tone; and drawing it upwards under the tongue, by the thyro-hyroid, shortening the length of the main exit tube, will render it higher. These movements can be felt by placing the finger over the larynx externally, and running the scale.

The epiglottis, by depression over the superior aperture of the larynx, will deepen the tone and render it duller, just as placing any covering over the end of any other tubular musical instrument will deaden the sound. The epiglottis doubtless conduces to the production of the pathetical warning tones of the minister, and to the rough, menacing tones of the ruffian; and is produced consentaneously with the lowering of the jaw and depression of the tongue in the production of these deep and hollow tones.

The arches of the palate and the uvula contribute to the modification of the vocal sound, as we well know from examples of congenital or pathological deficiencies; and too extensive an amputation of the uvula for hypertrophy or elongation is said in many instances to have been followed by deterioration in the quality of the musical tone. We sometimes see the arches of the palate vibrate powerfully in the production of the trill, and it would appear in some instances to be the chief agent in the formation of the trill, instead of vibration of the glottis.

In Tobold's latest work, *Die Chronischen Kehlkopfs-Krankheiten*, are given the deductions of a reliable professor of music, as to the modification and timbre of the vocal tones. These are to the effect that the chest-notes are characterized essentially as reed-notes, and the falsetto and head-notes as flute notes; thus confirming the opinion of Petrequin and Diday, arrived at long before Garcia's introduction of the laryngeal mirror as a means of observation.

In the flute instrument, tone is produced by the current of air only, and is modified by the length of the instrument. In the reed instrument, as we have already seen, the tone is produced by the vibration of metallic or membranous laminæ.

It has been a subject of a good deal of controversy, whether the primitive producer of tone in the reed instrument is the tongue itself or the air which is set in vibration. The tongue or reed does not seem to perform a secondary part in the formation of tone, for the strength of the tone will depend upon the nature and continuity of the impulse by which the reed is set in vibration.

That the vocal cords, although being but short membranes, can by their intrinsic vibration produce such full and powerful tones, is dependent upon the extraordinary elasticity of their structure, which it is impossible to imitate artificially.

The function of the vocal cords, in the formation of the chest-notes, can be well likened to that of the lips in blowing the trumpet. The lips are in themselves inelastic; but by voluntary muscular contraction they may be made to imitate membranous tongues. Now, while the lips are thus vibrating voluntarily, and producing tone, if we place opposite them an exit-tube (a horn, trumpet, trombone, etc.), we will not only find the tone become more sonorous, but it will be modified in the most varied manner, according to the mechanism of the exit-tube; and the entire character of tone heard will be due, not only to the mere blowing of air into it, but also to the reed-like oscillation of the lips. In this case the oscillating lips, imitating or acting for the time as membranous reeds, are the primitive medium of the tone; and not the current of air vibrating in the tube, as in the case of the flute.

Consequently, as the tongue or reed in the reed-instrument, and the lips in the blowing-instrument, we must regard the vocal cords as the primary educers of the tone, in the production of the chest-notes.

In the chest-notes the cords vibrate in great extent, and along their entire breadth. In the falsetto and head-notes, we see the glottis only as a more or less open slit, and the vibration is confined to the inner borders of the vocal cords, while the bodies of the cords remain tensely stretched, and do not vibrate at all—the inter-cartilaginous glottis remaining always closed. In the falsetto notes, the vibration of the cords, too, plays but a secondary part; and it is the vibration of the air that strikes them, which is to be principally regarded as the primitive element of tone.

To produce a normally formed tone, the cartilaginous glottis must remain completely closed, and the expiratory current escape through the ligamentous glottis only. In this way the entire escaping current is set in phonal vibration, and the tone will ring out fresh and powerful. But if the cartilaginous glottis be not closed, there streams out a second current which, in its exit,

mixes with the phonal current and renders it dull and veiled, instead of clear and decided, while at the same time more frequent inspiration becomes necessary, on account of the increased expiratory volume.

In the modification of the character of the vocal sound (timbre), the pharynx performs an important part, as by its lengthening, shortening, or contracting, it modifies the shape and length of the exit-tube. We distinguish two essential timbres, between which we have any quantity of gradation. The clear timbre is produced when the soft palate sinks to meet the mounting larynx. If this occurs to too great an extent, a disagreeable squeak is produced instead. When, on the other hand, the larynx sinks, thus lengthening the pharynx, the tone loses in clearness, but gains in roundness and volume, and acquires the dull timbre; and when this movement is pushed to excess, the tone is dampened and rendered rough.

If we compare the two registers, chest-voice and falsetto (the head register being only a higher modification of the falsetto), we find, in the chest-voice, that the phonal glottis appears closed linearly, in its entire breadth: the true vocal cords present a strong resistance to the expiratory current, are set in full vibration, and the modification of tone takes place by expansion and contraction of the lungs. In the falsetto voice, the phonal glottis is lancet-formed, showing an elliptical slit, and the escaping air meets with but a moderate resistance; and the higher falsetto notes occur through successive shortenings of the opening of the glottis from behind forwards.

The soft palate, the epiglottis, the ventricles of the larynx and the false vocal cords, are not directly necessary to the production of a chest, or falsetto note; they merely modify the tone formed in the glottis.

It is therefore clearly demonstrable why a very slight affection of the vocal apparatus may cause an important alteration in the production of sound, or even prevent it. Even a slight congestion and swelling of the true vocal cords will prevent vibration as perfect as that produced when the cords were sound. Swelling of the false vocal cords, especially when filling up the space of the ventricles, will cause them to act upon the true vocal cords as the dampers upon a stringed instrument, and thus prevent the full vibration of the true vocal cords, even when the latter are perfectly sound.

The limits of a journal article, in the present series, preclude as full a discussion of the physiology of voice, with reference to the phenomena of musical tone and mutism, as the writer would have liked to indulge in; and therefore he has but selected from the material at his disposal, such as, being confirmed or suggested by ocular observation upon the living human larynx, most fully expresses the views of recent observers (in this department of physiology, who have availed themselves of the laryngoscope in their investigations); and the greater portion of the present article has been taken bodily from the work of Tobold, previously referred to. It is necessary to have a distinct idea of the mechanism of the vocal apparatus, in the normal performance of its functions, to be able to recognise and appreciate deviations occurring in disease, especially if the attempt is to be made to correct them. The import of this observation will be acknowledged when we study the subjects of aphonia and dysphonia.

But the larynx is also greatly concerned in respiration. The appearance of the glottis, under these circumstances, as seen mirrored in the laryngoscope, is as follows: During ordinary quiet respiration, the glottis remains moderately opened, lozenge-shaped, gently dilating with an inclined movement at each inspiration, and contracting again in the expiratory movement; the arytenoid cartilages being separated. When a forced inspiration is taken, the vocal cords and the arytenoids become separated to their widest extent, and the form of the glottis is changed to a trapezoid; at the same time, the epiglottis becomes more erect and continuous with the anterior wall of the trachea, a position which affords the best view of the conoid ligament where the subject is young enough for it to be recognised, as well as a more extended view down the tube. The extensive motility of these parts can best be observed by taking a deep inspiration, when the view above described will be presented; then following it, by intonation, the glottis closes promptly, the true vocal cords stretch towards each other, and the arytenoids become closely pressed against each other.

The whole mechanism of closure of the larynx, in the act of swallowing, cannot be observed in the laryngoscope, for the simple reason that one cannot swallow with his mouth wide open; but the movements can be induced artificially by going through the preliminary motions of swallowing, retching, etc. Of course, respiration is stopped by complete closure of the glottis from approximation of the true vocal cords; then, as the movement is continued, the false vocal cords become closely applied, and the epiglottis falls promptly, its belly tightly pressed upon the false vocal cords, its free border reaching beyond the arytenoids, and its lingual surface undergoing a linear indentation in the middle line, giving it much the appearance of a double cap to the spout of a molasses jug. Some persons have the facility of controlling these movements, so as to demonstrate the triple action in distinct succession: the closure of the glottis, the apposition of the false vocal cords, and the depression of the epiglottis.

In cases of aphonia from paralysis, the sole factors of this closure are the false vocal cords and the epiglottis; where the epiglottis has been destroyed, the factors are the vocal cords, true and false. In these cases, the combination of muscles, called a sphincter of the larynx in the last article, compresses the false vocal cords and the ary-epiglottic folds, puckering up the laryngeal entrance.

Original Lectures.

LECTURES ON PUERPERAL CONVULSIONS.

DELIVERED IN CHICAGO MEDICAL COLLEGE,

By W. H. BYFORD, A.M., M.D.,

PROF. OF OBSTETRICS, ETC.

LECTURE IV.

Treatment.—The two main indications in treatment are: First, the removal of hyperæmia of the brain and spinal nervous centres; and, second, removal of the uræmia.

To overcome both these morbid conditions is very desirable but sometimes impracticable, yet we can generally entirely get rid of one of them and thus avoid the commencement or continuance of the paroxysms.

The treatment is very properly and naturally divided into the medical and obstetrical.

Although possibly not the most important, it is most convenient to consider the medical treatment first. The application of treatment is modified by the time when instituted; that is, either as preventive or curative. As I have endeavored to show, we may often determine the presence of a predisposition to puerperal convulsions quite conclusively some days, and even weeks, before the supervention of an attack; and not unfrequently, by proper treatment, entirely avoid the development of them.

We will often be able to accomplish *one* of the indications of a cure by preventive measures, viz. to remove hyperæmia of the nervous centres. The means to accomplish this end are bleeding, the administration of cathartics, diaphoretics and diuretics. When the patient is plethoric, with a red injected face, a full and slow pulse, blood-letting should be resorted to. We may bleed the patient until these conditions are removed or very much reduced. I hope I may be allowed to remark that when the predisposition is certainly present, we are justified in using, nay the case demands energetic measures, and that we ought not to be deterred from the employment of them for fear of inducing premature delivery, for really this would add to the chances of both the patient and fœtus. And for fear of being misunderstood by the student, I will repeat the main items diagnostic of the predisposition, viz. œdema of the *upper* part of the body, face, or limbs, or all together, albumen in the urine, and the various nervous symptoms I have mentioned. When to these are added those of decided plethora, an active antiphlogistic medication is generally very beneficial. One decided venesection in the sitting posture, until approaching syncope is observed, will sometimes do much good and entirely avert the attack. But active catharsis is also attended with very satisfactory results. The compound powder of jalap is one of the best of cathartics at such times. It should be administered in sufficiently large doses to cause copious watery evacuations. Should the patient not be decidedly plethoric, we may, with propriety, omit the bleeding, but the cathartic should be given. This should in either case be succeeded by the wine of colchicum in decided doses every four or six hours, and at least once a day the patient should have a steam bath to cause free diaphoresis.

At any stage of this treatment nervous suffering should be promptly relieved by opium. The Dover powder is a good form. Very often such treatment is followed by premature labor, and when such is the case the labor is much less apt to be attended by this dreadful complication. I think this plan is very much more appropriate than an immediate resort to the intentional induction of premature labor without first reducing the cerebral hyperæmia. This cerebral hyperæmia should be held up to us as affording one of the most valuable indications of treatment; very often its removal is sufficient to render a very threatening case safe. The preventive treatment I have recommended is not always followed by premature labor, as this process may not take place at the end of term. Sponge baths of acetic acid, friction with acetic acid, and acid drinks and medicines, may be used with the hope that they may enter the blood and neutralize the ureal accumulations in that fluid.

During a Paroxysm.—The first thing that should be attended to during the paroxysms is to prevent the injury which so frequently results to the tongue. A large cork, or a soft pine stick, should be placed between the molar teeth on one side while the jaws are separated, and thus retained, until the convulsion ceases. We ought not to be betrayed by any excitement into the use of a spoon-handle or other metallic substance, lest damage may be done to the teeth. The clothing should be loosened, so that the neck, body, or limbs, may not be constricted by it. The throat must be made entirely naked when practicable, and we must observe that the violent and irregular movements do not twist the clothing about some part of the person to an injurious degree. The attendants ought not to restrain the movements of the patient too greatly; indeed, perfect freedom to the whole body should be allowed when it does not become clear that it will result in throwing the patient off the bed or bruising her person. It is very harmful, for instance, to take hold of the limbs and try to hold them still. The bed should be large and firm enough to bear the weight of the attendants, if necessary. Plenty of air should be admitted into the room, and the latter should not be too warm. The face may be sprinkled or washed with cold water. I have tried to interrupt the convulsions by dashing the face suddenly with ice-water, but have not seen any effect from it that was desirable.

Inter-paroxysmal Treatment.—It is a matter of the greatest moment to prevent a recurrence of the paroxysms; if this can be done we are almost sure of success. The fewer the convulsions the less the danger, should be an ever present fact with us. It is the frequent repetition of them that produces the fatal effects upon the brain. By the judicious use of chloroform we may prevent them from returning in a great many instances, if not all of them. Dr. Braun, of Vienna, recommends us to give chloroform as soon as there is any sign of a supervening paroxysm, and continue it until sound sleep is induced; but I am sure that to administer in this way we shall fail to get all the good effects from its use that are practicable, for in many instances the premonition is so short we will not prevent the convulsion. The only safe way, and the one I now practice and would strongly recommend, is to keep the patient under its influence all the time sufficient to prevent a manifestation of the premonitory symptoms.

This direction may be followed by sitting by her constantly, and administering the anæsthetic about every ten minutes generally, but sometimes it may be necessary to have a small amount mixed with the air inhaled constantly. The intention is to very much lessen, if not entirely subdue, all reflex excitability, and keep it controlled until the cause of the trouble, uterine pressure, can be removed. The effect of the chloroform is to remove, or rather to subdue, the explosive excitability of the nervous centres caused by the circulation through them of the urea, carbonate of ammonia, or whatever other exciting stimulant has resulted from the retention of substances that ought to have been excreted by the kidneys. It is not likely that the chloroform chemically neutralizes the poison in the blood, but that it renders it inoperative by producing a more powerful but antagonistic influence upon the brain and medulla. It is not at all directly curative, it only suspends the action of the mischievous agent until curative means may be made effective in removing the pathological conditions upon which the convulsions depend. And I must insist, in *all* cases of uræmic puerperal convulsions, where there is enough excitability to keep reproducing the paroxysms, chloroform is applicable and demanded, whether attended with a uræmic, paralytic, or even apoplectic state of the brain and spinal cord or not. It is precisely to control this morbid excitability of the nervous system that it is used; and although I have been governed by this principle for several years, I have never seen any unpleasant effects from its use in convulsions. And whenever I had cause to regret anything of my management of this most excellent remedy, it was that I had been too sparing with it, that I had not kept my patient sufficiently under its influence. It would hardly seem necessary to say that it is entirely useless during a paroxysm, except in very rare instances, in which respiration continues, because it cannot be inhaled as respiration is suspended, and that it is injurious immediately after the paroxysms, while the face is livid with carbonated blood. We wait until the face loses this asphyxiated appearance, and the blood is again charged with its usual amount of oxygen. As soon as this state is brought about we give

the chloroform continually, and maintain an anæsthetic condition that will keep the patient entirely free from the convulsions. She should never be allowed to come out of this state until delivered, if this can be done by any allowable means, even should it require twenty-four, thirty-six, or forty-eight hours. After she is delivered she may be treated generally without further use of chloroform, but if the convulsions recur we should resort to it at once, and keep it up until renal and intestinal secretion is fairly established. Keeping the patient thus constantly anæsthetized beyond the convulsion point, we ought to institute curative measures with as much energy and activity as possible.

Blood-letting is one of the first things to be thought of. The intention in using it is to reduce or remove the cerebral hyperæmia, by lessening the amount of blood and reducing the arterial and cardiac *vis à tergo*. To effect this we must take a large quantity compared to the amount for other conditions of the system. From twenty to forty ounces will be required in one or two operations. The pulse must be affected by it. Sometimes a convulsive paroxysm occurs while the patient is bleeding; this ought to be prevented by chloroform. I have several times bled patients under the influence of chloroform. The anæsthesia should be slight during the bleeding, but sufficient to prevent the paroxysms, and the patient must be more closely watched. She should be supported in a sitting posture while the blood is running, and as soon as the pulse becomes decidedly quicker, we should lay her down and stop the blood, and if necessary repeat it when reaction has resulted. One copious or two moderate bleedings is allowable almost always, and in very plethoric patients two or more copious bleedings. Those old worthies in the profession, Gooch, Armstrong, and others of like stamp, cured many cases of puerperal convulsions by powerful depletory treatment alone. Gooch thought bleeding *the* remedy. As I have endeavored to show, the apoplectic congestion of the brain is an important item, although not, as was supposed by the older authors, the only item. It is probably of secondary importance, but its removal goes a great way towards a cure. I insist that bleeding is one of the very best curative measures, and should be considered in all cases. At the same time that we bleed, or if we do not think best to institute blood-letting, we may, with great propriety, administer an active cathartic. And in doing so we are to remember that promptness is a necessary quality; for the longer the bleeding is delayed, and the longer the cathartic is in operating, the more valuable time is lost.

If we can procure copious and early catharsis without pain, we make a very favorable impression. The medicine I have used most, and still continue to recommend, is croton oil. I usually administer one drop in an emulsion every hour until it operates thoroughly, which, if good, it will do after two or three doses. This treatment will seldom fail to very much modify the severity of the symptoms, and in very many instances completely arrest the convulsions. I know that before the days of chloroform, at a time when the pathology of these cases was not as well understood as now, twenty-five to thirty years ago, many were cured by this treatment; and I am cognizant of two cases in which the convulsions were arrested, and delivery did not take place in one until three and the other five weeks afterwards, each patient carrying a dead child that long, and being delivered without interference or further convulsions. We then bled in both arms in a full stream until there was a close approach to syncope, and sometimes twice, and even thrice, in the same case, and gave the croton oil cathartic at the time we bled. And with all deference and respect for those who have learned to do better without than with bleeding, I must assure the profession that such success as attended our efforts then would not put them to the blush now. I am afraid that the tendency now is to magnify to an undue extent the effects of uræmia, and depreciate the importance of cerebral hyperæmia. And in saying this I feel assured that a proper estimate of uræmia will make it a very dangerous element of the disease, while I think I but express the conviction of the most judicious and thinking portion of the profession, when I say that we have no remedy for it that acts with anything like the promptitude that those do which prove effective in the cerebral congestion. That we may very much modify if not relieve, the latter, in a few hours, nay minutes, while the uræmia cannot be remedied in less than *one or two days*. After proper depletion, or with it, cold to the head, ice in bladders, or india-rubber bags, will aid in the same thing, reducing cerebral congestion; and opium administered in sedative doses may so affect the nervous centres as to materially lessen their violence, it operates somewhat in the same manner that chloroform does by diminishing the excitability of these organs. It does not exert any direct curative power, it only holds the convulsions in abeyance until the uræmia and hyperæmia are removed. Acids undoubtedly act beneficially by attacking the irritating compound circulating in the blood. We must not expect too much from them, however. Acetic and citric acid drinks, vinegar baths, acid compresses over the abdominal surface, back, etc., should be resorted to as much as in the nature of the case is practicable. Then we should resort to diuretics and hydragogues of a particular character. Colchicum, or its preparations, is a powerful diuretic, and has the reputation of inciting the kidneys to the secretion of urea. When given in large doses it proves a hydragogue cathartic and emetic. A teaspoonful of the vinous tincture every hour, until perceptible effects result, and then continued in such doses as the patient can bear without great irritation in the alimentary canal, is the usual mode of using it here. Other diuretics would probably be useful.

A very important part of the treatment is obstetrical. If the views above expressed are true, so long as the uterus maintains its extreme size, the pressure on the large vessels, and the vessels and substance of the kidneys, is continued, the evil working cause is kept up; and while the subsidence of that organ in the pelvis and the consequent relief to the tension of the abdominal muscles, takes off some of this pressure, and sometimes this extends the critical period, if it does not entirely arrest it; yet, it is not generally sufficient. And the patient is not usually safe until it is emptied.

The obstetrical treatment will vary somewhat, owing to the time when the convulsions occur. During pregnancy, any time before term, premature labor is apt to supervene as the effect of the convulsions or the condition of the system upon which they depend. And should this be the case it may be accelerated by means which I shall presently indicate; but if there are no signs of labor, the treatment should be wholly medical, and may be conducted as I have directed above. If labor has commenced and dilatation is slow and difficult, we should dilate the os by artificial means. The only one I have ever resorted to is the finger. By placing one or two fingers in the mouth of the uterus and gently but constantly keeping up pressure upon it from within outwards, we will very much shorten the stage of dilatation. The effort to dilate should not be abated during pain, nor in the intervals, but a constant fatiguing pressure made. So soon as the os is dilated to two inches in diameter, we ought to rupture the membranes

and allow the liquor amnii to flow out. This will generally add energy to the contractions and somewhat lessen the size of the uterus. We should not desist from dilatation until the head has emerged from the cervix entirely. If the head is not readily expelled, we must apply the forceps and assist by judicious traction. If labor proceeds, however, with reasonable activity, and we can succeed in controlling the convulsions, we must abstain from operative procedure entirely. An indispensable condition in all cases where it is necessary to accelerate delivery by any means whatever, is to keep the patient deeply under the influence of chloroform, so much as is necessary to preclude the danger of additional irritation thus caused, bringing convulsions. To dilate, rupture the membranes, and use the forceps, should be the extent of our interference, unless when the feet, knees, or breech presents. Where either of these parts can be seized, we may aid very materially by traction upon it. Craniotomy is not justifiable until we can demonstrate the death of the fœtus, unless indicated by circumstances independent of the uræmia, such as disparity of size between the head and pelvis, ineffectual efforts with the forceps, etc., etc. Neither are we to think of turning. In fact, we must do no more than is absolutely necessary, and do that in such a way as to cause the least possible irritation, and be sure to use chloroform liberally. I say that I have never used anything but my fingers to dilate the uterus, but there is a variety of very efficient means used for this purpose. The compressed sponge is one of the means very efficient, quite handy and available. Dr. Barnes's dilators are also very eligible and efficient. These consist of gum elastic air bags of different sizes. The smallest should be introduced into the cervix empty, by means of the probe, and then inflated through a tube attached to it; in an hour this may be replaced by the next larger, and so on until the mouth is fully dilated. If the compressed sponge is used, a piece large enough to pass easily into the cavity of the cervix may be introduced, and in three hours a larger one if necessary, and so on until the process is completed.

Convulsions commencing after labor is finished, necessitate an examination of the uterine globe externally and internally, by introducing the finger into its mouth to see that the organ is well contracted, and there are no imprisoned clots that are causing irritation. If contraction is not good and blood coagula accumulate, we may use friction above the pubes and give ergot enough to secure the desired effect. Depletion, cathartics, diuretics and opium, with chloroform, are to constitute the treatment, as in the other condition above mentioned.

Progress of Medical Science.

ACCIDENTAL AND CONGENITAL ATRESIA OF THE VAGINA; THE MODE OF OPERATING FOR SUCCESSFULLY ESTABLISHING THE CANAL.—Dr. Thos. Addis Emmet, Surgeon of Woman's Hospital, New York, communicates an article to the *Richmond Medical Journal*, from which we extract the following:—After a review of the literature on this subject, we learn that the result of surgical interference for the permanent relief of accidental occlusion—a consequence of inflammatory action—is favorable in proportion to the extent of the vaginal tract involved, and that the risk of inflammation, as a sequence, is generally in the same ratio. We find, moreover, but few congenital cases recorded, where the canal has remained permanent after an operation, and from the frequent occurrence of pelvic inflammation or peritonitis resulting, the operation for an artificial vagina is now universally regarded as one of a very grave character. It is my belief that, could we learn the after history of the cases recorded, success would prove an exception to the rule. For it has been my experience, without an exception, that the operation has eventually failed where the parts have been divided by means of the knife, in spite of every effort to keep the surfaces separated by bougies, or any other means which would be resorted to for the purpose. Unless some portion of the mucous membrane has remained intact at the upper part of the canal, the plug will be gradually expelled by adhesion of the surfaces from above downwards, until the original condition is attained. When merely a section of the canal has been divided, the required diameter can be preserved so long as a bougie is retained, but after discontinuing its use, the incised tissue will gradually contract, until the false passage becomes obliterated, or reduced to a mere sinus. As a result of a large experience in operating for vesico- and recto-vaginal fistulæ, I became impressed with the fact that in the preparatory operations, when it was necessary to divide extensive bands of adhesions before the edges could be approximated, inflammation rarely followed a division by scissors, or laceration by means of the fingers. In addition, it was observed, that with less hæmorrhage, the vaginal tissue, when divided by scissors or lacerated, had not the same tendency to contract during the process of healing as when separated by means of a clean cut. I became so fully impressed with these facts, that I have for several years entirely discarded the use of the knife in all operations about the female pelvis, wherever it is possible to do so. I am aware that the impression generally received is in opposition to this experience, that the risk of inflammation, and I may add of pyæmia, is lessened by the laceration of the tissues; but a large number of the profession have witnessed the practical results in the hospital, and its records will bear me out in the assertion.

A NEW APPARATUS FOR MAKING EXTENSION AT THE ANKLE-JOINT.—Dr. Julien S. Sherman, of Chicago, describes an improved apparatus for making extension at the ankle-joint. In order to construct it properly, a cast of the patient's leg, from the knee to the ankle, should be taken in plaster of Paris. It is not necessary to include the foot. A piece of sole leather should then be soaked in water, until perfectly soft and pliable, and then moulded and firmly tied upon the cast. It should remain in this condition until thoroughly dry, when it will be found to form a strong socket, *exactly* corresponding to the shape of the leg from which the cast was taken. A steel sole is then cut, the shape of the bottom of the foot being somewhat narrower beneath the instep and heel. From this, and riveted to its under surface, rises, on either side, a steel rod, bent to the shape of the limb; upon its upper two-thirds a screw is cut. This rod is received into a tube, which is attached to the socket. The screw carries a nut, by which the extension is regulated. The rod is braced to the sole by an additional strip of steel on either side. The socket is lined with buckskin and provided with eyelets and lacers. Padding is not necessary, as it corresponds so accurately to the limb that the pressure is easily tolerated. A layer of *sponge rubber* is placed upon the sole, which gives an elastic surface to strap the foot upon, and one which will not *pack or become hard*, as is the case with most substances used for this purpose. The apparatus is applied by first adjusting and lacing the socket; the rods are next inserted in the tubes, and the steel sole brought up against the bottom of the foot; adhesive straps, an inch in width and sufficiently long to pass around the foot and heel, are next

applied, so as to bind them firmly down to the sole; extension is then made, by turning the nuts upon the rods. By this means, all pressure upon the inflamed surfaces will be overcome, and the deformity of "talipes equinus," so frequent in diseases of this joint, prevented, and the best possible condition for recovery obtained. In walking, the patient bears all his weight in the socket, relieving entirely the ankle-joint.

Singular Parasite.—Dr. Ernst Schmidt exhibited to the Chicago Medical Society a specimen of a very unusual parasitic worm, with the following history:—An American girl, ten years of age, weakly, and of scrofulous diathesis, had suffered for some time from capricious appetite and pain in the upper portion of the abdomen. Two weeks ago she complained of pain on the left shoulder; at the seat of pain there soon appeared a slight elevation, tender to the touch, slightly red, from which, in a short time, a small worm was observed, endeavoring to escape. If disturbed, the worm withdrew its head beneath the skin; by gentle pressure, however, it was forced through the small opening it had made. A similar swelling appeared behind the left ear, from which another worm made its escape. Thus far, eight elevations have appeared in different portions of the body, from which five worms have been secured. Some of these elevations were neither red nor very tender on pressure. Palpation gave the sensation of a foreign body under the skin. The efforts of the worms to pass through the skin caused no pain or hæmorrhage. The small opening closed readily, and the elevation soon subsided. The child, during this time, was nervous and irritable, the pulse being, at times, as low as 40 per minute. The application of mercurial ointment caused the elevations to disappear. In all cases where this was applied, the worms seemed to pass upwards from their original position towards the head. The child was not in the habit of eating either raw meat or vegetables. There were no indications of other parasitic worms in the child or other members of the family. The worms were about five-eighths of an inch in length, quite transparent, and divided into eight sections, with an alimentary canal running nearly straight from the anterior to the posterior extremity. The mouth, as examined with the microscope, presented no evidences of apparatus for suction or boring.—*Chicago Medical Journal.*

Extirpation of the Uterus.—Dr. T. Wood, Surgeon to the Commercial Hospital of Cincinnati, reports in the *Cincinnati Lancet and Observer*, a very interesting case of extirpation of the uterus. The patient was a widow, 28 years of age, who was admitted into the Commercial Hospital October 1, 1866. Her abdomen was enlarged about the size of the sixth month of pregnancy; the tumor was hard and smooth, and occupied the median position of the body; was only slightly movable; she had a constant leucorrhœal discharge from vagina, and frequent attacks of pain of a lancinating character, with painful micturition and great difficulty in procuring a passage from the bowels. Had always been a healthy woman; is stated to have aborted at seven months, seven years ago; three years ago she had a severe attack of rheumatism, and immediately upon the subsidence of acute symptoms of this disease, a small tumor made its appearance and has been steadily increasing in magnitude until it has attained its present size. The diagnosis being fibrous tumor of the uterus, its removal by abdominal section was resolved upon, and she was put upon tonics and a regulated diet.

On the 31st of October, she being in good general health, the operation was performed in the following manner: After being placed under the influence of chloroform, an incision was made over the most prominent portion of the tumor, and directly in the median line of the body—extending from the umbilicus to within an inch of the pubes. This cut was rapidly deepened; the fascia, and finally the peritoneum, divided upon the director, when the glistening and smooth surface of the tumor was exposed; it was entirely free from adhesions, and after some slight traction escaped through the opening; was pyriform in shape, and attached in the median line by a comparatively slender pedicle. After tying an artery and a large vein which passed up at the posterior portion of the tumor, and applying ligatures to the ovarian arteries of each side, two double ligatures were then passed through the pedicle by means of needles, and firmly tied; the tumor was then removed by a few strokes of the scalpel; hæmorrhage was very slight, not over ʒ ii. having been lost during the entire operation; there was no protrusion of the bowels, they being easily retained in position by cloths wrung out of warm water. After the removal of the tumor, the pedicle was returned into the abdominal cavity, the ligatures being collected and brought out at the lower end of the cut. After careful sponging, the oozing of blood having entirely ceased, the lips of the wound were brought together, and retained by means of silver pins and twisted suture. The wound was then dressed with cloths wrung out of cold water, and she was removed to her bed. The case did well until the latter part of January (precise date not given), when death took place. This, to the best of our belief, makes the twenty-sixth fatal case out of thirty-three operations performed.

On the Use of Sulphite of Soda in the Treatment of Erysipelas.—Dr. Addinell Hewson stated that he had been using the solution of sulphite of soda as a local application in erysipelas since February, 1864, and had obtained results from it, in the various forms of that disease, which were to him both interesting and surprising. He had been induced to try it from the representation made by Prof. Polli of its influence in destroying all diseases of a cryptogamic or animalcular origin—a source to which recent researches would lead us to suppose erysipelas was due. At first he administered it internally, in doses of ten grains every two hours, as well as applied it locally; but the effects of the local use were so prompt and decided that he has now abandoned its internal administration altogether. In extensive trials of this remedy, both in hospital and private practice, he has never seen it fail when thoroughly applied before the deep planes of cellular tissue had been invaded by the disease. Under the latter circumstance, no positive curative results were of course to be expected from its mere external use. But before such parts had become affected, a solution of ten grains of this salt to the ounce of water, when thoroughly applied on lint all over the surface affected, and to a considerable distance beyond it, and covered with oiled silk to prevent the evaporation of the solution, had not only produced a decided bleaching effect on the discolored surface in every such instance in the first twenty-four hours of its use, but had invariably destroyed all traces of the disease in forty-eight hours from its first application. The result was the same, whether the application was made in the traumatic or idiopathic form of the disease. He had thus cured twenty-seven cases, seven of which were of idiopathic erysipelas. Even in the cases where the deep planes of cellular tissue were involved as well as the surface, the disease on the surface was always apparently affected by the application. It was most positively bleached in all instances, and in many was evidently destroyed, within the period above stated, even whilst that in the deeper parts proceeded on steadily to suppuration.—*Trans. Coll. of Phys. of Philadelphia.*

THE SOCIAL CRIME AS AFFECTING OUR NATIVE POPULATION.

So prevalent is the belief that criminal abortion is extensively practised, that arguments are unnecessary to further establish it. During many years past the subject has claimed the attention of medical men in every country; resolutions condemnatory of the crime have been passed by medical bodies everywhere; papers almost without number have been written upon it; legislation, religion, morality, and physical well-being, have all been in turn appealed to; but all efforts to arrest its progress have not only been futile, but worse than this, we have undeniable assurances that it is on the increase. Formerly the crime was confined principally to those who were the victims of illicit intercourse, and who, maddened by the fear of exposure and its consequences, were ready to resort to any measure, however desperate. Now, however, wives and mothers are added to the list, and are better versed in the abominable art than their erring but certainly not more culpable sisters. We do not propose to remark upon the general subject of abortion, as it has long since been worn threadbare; in fact, we should consider ourselves as having no excuse to allude to its general prevalence and increase, were it not that some new facts have lately transpired which invest it with no little interest These facts are of the utmost importance as bearing upon the question of increase in population, and are also of special concern to us in reference perhaps to the propagation of our native stock. We shall not pretend to show the direct relation between the prevalence and increase of abortion, and the effect which it has upon the comparative decrease of native-born Americans, but shall simply present the facts of the case, and give our readers an opportunity to judge for themselves.

We are thus far enabled to see the results of an examination of this question only in a single State, that of Massachusetts; but judging from the care with which the several conclusions have been arrived at, they should certainly have no inconsiderable weight. The census returns of that State prove that the increase for the last twenty years in the number of inhabitants has been in accordance with a given ratio. This is certainly well enough, as far as it goes; but the investigations of DR. NATHAN ALLEN, of Lowell, tend strongly, if not conclusively, to prove that this increase is made at the expense of a natural growth of our native population. This gentleman has given considerable attention to the subject, and makes some rather startling statements bearing upon it. He maintains that the increase of inhabitants of that Commonwealth during the past twenty or thirty years, has been confined principally to those localities where mechanical, manufacturing, and commercial business has been carried on, the purely agricultural districts being more or less stationary in population. But this increase has been found to be made up largely of the foreign element, either from immigration or by the greater number of births. "It is a fact," says he, "that the foreign class will have on an average about three times as many children as the American. On the other hand, if we take the counties or towns where there has been but little increase of population, we find that they are made up mostly of American stock. In fact, a careful analysis of the census reports of different periods shows that this increase in population in the State follows almost invariably in the same line and in the same proportion as the foreign element has been introduced or increased." That this would seem directly traceable to the number of births exceeding those of deaths, the majority of the former being due to the foreign element, he asserts as the result of a careful examination of the Registration report, that the counties containing the least foreign population now return more deaths than births; while in those cities and towns having the greatest foreign population, the reverse is true.

Acknowledging the difficulty in discriminating, in the Registration reports, between the deaths of Americans and foreigners, since all those born in this country are counted as natives, he believes that this can be in a great measure surmounted by a careful examination of the books of the undertakers, superintendents of burials, and city clerks, and has proved this to be so by such a perusal of the mortuary documents of the cities of Lowell and Lawrence. In order to throw out all objections against the force of the Registration reports for 1864–5, which were made during the period of the war, he goes back to a period considerably antecedent, and proves that for a long time there has been a relative decrease of births with the Americans. This is the language of the report:—"In the colonial census of 1765, taken one hundred years ago, when the population was purely American, the total inhabitants were then two hundred and twenty-two thousand five hundred and sixty-three, and the number under sixteen years of age returned as one hundred and two thousand four hundred and eighty-nine—almost one-half of the whole population. Now it is estimated that only about one-third of our population is under fifteen years of age. Accord-

ing to this estimate, a careful analysis of the natural proportion of the children to each class will show that scarcely one-fifth of the Americans are at the present time under sixteen years of age. This makes a surprising difference in the relative number of children of the same people at the two periods, 1765 and 1865."

For the purpose of showing that there has been a progressive decline in the number of births among Americans during successive periods, he has chosen to refer to the records of some towns which have been kept over a period of two hundred years, and have been carefully examined in reference to determining the relative numbers of children of the different generations. "It was found," he remarks, "that the families comprising the first generation had, on an average, between eight and ten children; the next three generations averaged between seven and eight to each family; the fifth generation about five, and the sixth less than three to each family." This is a most striking falling off of births, which cannot reasonably be explained on the score of a physical degeneration of our race. There are, it is true, influences at work which did not exist when our grandmothers and great-grandmothers were alive; the advance of civilization and the consequent thirst for indulgence in luxuries have certainly left their mark upon the female race of the present day, and have in the aggregate lowered their standard of vitality; but despite all this, we cannot be made to believe that this can even begin to account for the discrepancy. A candid examination of the circumstances of the case will not leave us long in ignorance of the primary cause. The one cause which we are forced to accept, and which, alas! there is too good reason to believe is the only true one, is a settled determination on the part of large numbers of the married to have no children, or at least a very limited number. When we couple this conviction with the fact set forth by the labors of Dr. Allen, that the native stock has a marked tendency to decrease, at whose doors can the blame be for the most part laid? We hardly know which to deplore the most—the growing tendency to lessen the numbers of a noble race, or the depravity which invites the sacrifice! "What a change," says our statistician, "as to the families since those olden times! Then, large families were common—now the exception; then it was rare to find married persons having only one, two, or three children; now it is very common! Then it was regarded a calamity for a married couple to have no children; now such calamities are found on every side of us—in fact they are fashionable!"

If this be so with other States, and we seriously suspect it, a very melancholy and painful fact is brought to light. We have no means at present of determining the relations of native new-born with those of foreign extraction in our own State; one thing at least is certain, and that is, that the aggregate number of births has, by the census of 1865, been shown to be disproportionately small. Sixty-six out of every one hundred families in the City and State of New York have either no children at all, or but one or two. The lesson which we have thus far learned is one that is of immense importance, and should stimulate a searching inquiry into the condition of every State in the Union. Such an investigation has already been set on foot by Dr. Hough, who has the superintendence of the census of the Empire State, and there is a good promise of something substantial being done; others in like positions should do the same, and the results of their common labors in this particular direction may soon settle a point of the greatest moment to every commonwealth in our land.

The sessions of the Medical Colleges have closed for the season; the usual number of addresses and benedictions have been pronounced; and the young medical man, with diploma in hand, has been politely courtesied out upon the cold and uncharitable world. He has been told that his profession is an honorable one, and that nothing but success awaits him. While we hope he will appreciate the true force of the former, we think it our duty to undeceive the too credulous one in regard to the latter. A distinguished professor is in the habit of advising his pupils to study well the cases which may present themselves in the early part of a professional career, and at the same time of remarking that they will have an abundance of time so to do. This gives a clue to the real chances which any young medical man has of at once getting into a lucrative practice. Between him and success lie many obstacles, and much time; and in order to get over them, it is well that he should understand what to expect. Disappointment at the start has been the lot of the most brilliant men we have among us, and no extra talent which the young doctor may deem himself possessed of, is likely to change the rule. Practice will always come after a while, but only after a while; and every one who desires to do credit to himself, to his calling, and to his patrons, should at the very outset of his career

"Learn to labor and to wait."

He who does otherwise, and starts in a different way, and gets, by some seemingly lucky chance, into a business at once, not only does not deserve it, but will never, in the end, be a really successful practitioner. He can never get time to study as he should; he begets a careless habit of prescribing; his knowledge is always deficient, and he never rises above mediocrity. Let this thought comfort the young physician during the first year or two of his practice.

The appointment of Prof. Benjamin Pierce, of Harvard University, to succeed the late Prof. Bache as Superintendent of the Coast Survey, is a good one, and will be hailed with satisfaction by the majority of the scientific men of the country, to whom his superior attainments and his fitness for the position are well known.

We are greatly pained to see the use made of the name of one of our esteemed Brooklyn physicians, which we find in the "*Daily Eagle*" of that city of a late date. There is an account of more than two columns, headed "A Medical Phenomenon, a young lady of this city lives eighteen months without food; wonderful exercise of clairvoyant power. * * Extract from the diary of her physician." The reporter states that "the lengthened prostration of the patient, her remarkable functional derangement and peculiar powers, induces the medical attendant to allow the added indorsement of his medical name and reputation." Then follows the name and address of the physician, who is said to be "of no inconsiderable reputation." We hope that the reporter has presumed too much in publishing this *quasi* advertisement, and that the medical gentleman in question will promptly disavow any such use of his name as is here made. The case is worthy a scientific notice, in a medical journal, where it would do some good. As it is, now, it can only satisfy a morbid curiosity and give an unenviable notoriety to the physician in charge. This disgusting system of advertising, if allowed by our profession, will soon degrade us to the level of the quacks, who regularly occupy columns of our daily press.

Reviews.

THE BRAIN AND CRANIAL NERVES, SHOWING THEIR ORIGIN AND ARRANGEMENT. A Chart. By THOMAS S. BUTMER, Undergraduate in Medicine, Toronto University, Canada. 425 Wellington Street, Montreal, Canada.

THE compiler of this chart, whose industry we commend, has well achieved the object had in view of speaking to the eye, and, through that medium, of more profoundly impressing the memory. It will constitute a very useful piece of furniture for the lecture-room, and would not be out of place in the offices of those desirous of keeping bright their anatomical lore.

MEDICAL RECOLLECTIONS OF THE ARMY OF THE POTOMAC. By JONATHAN LETTERMAN, M.D., late Surgeon U. S. Army, and Medical Director of the Army of the Potomac. New York: D. Appleton & Co., 1866. Pp. 194.

SURGEON LETTERMAN, who will long be held in grateful remembrance for his administrative ability as medical director of the "dear old Army of the Potomac," amid all its strangely chequered fortunes, has succeeded in giving a very interesting, not to say fascinating book. He writes in a perspicuous, elegant style, and we venture to assert that but few who open his volume of medical annals, pregnant as they are with instruction, will care to do otherwise than finish them at a sitting. To old campaigners the tribute will be indeed welcome; while the "intelligent people," to whom he appeals in his preface, cannot fail to appreciate the labors of that most necessary adjunct to a well appointed army—an intelligent, and therefore efficient medical department.

AN INTRODUCTION TO PRACTICAL CHEMISTRY, INCLUDING ANALYSIS; by JOHN E. BOWMAN, F.C.S., late Prof. of Practical Chemistry in King's College, London. Edited by CHARLES L. BLOXAM, F.C.S., Prof. of Practical Chemistry in King's College, London, etc., etc. With one hundred and seven illustrations. Fourth American, from fifth Revised London Edition. Philadelphia: H. C. Lea, 1866, 12mo., pp. 351.

THIS work does not pretend to be more than it really is, an introduction to practical chemistry. It is concise, all theoretical questions are avoided, and is just what is specially needed by the student who wishes to work satisfactorily in the laboratory. The symbols and equations which were given in the previous editions have been omitted, the editor wisely concluding that a much better plan for the student would be to frame them for himself. The chapter on mouth blow-pipe analysis has been much improved, in fact rewritten, which is virtually the case with that portion treating of examinations of unknown substances with the blow-pipe. Besides this, the several metallic and non-metallic bodies have, for convenience of consultation, been arranged alphabetically, and, altogether, give us a very fair dictionary of blow-pipe tests. The reactions of metals have been rearranged, and are much more convenient for study than in the former editions, their claims being considered in the same order in which they are separated from a solution, and not in the inverted order as heretofore. Qualitative analysis receives its share of consideration, and the tables introduced into the appendix for the rapid analysis of simple substances, will be found of great value to the beginner. The illustrations are good, and give a fair insight into the different methods of manipulation, a proper understanding of which makes the study of chemistry so attractive, intelligible, and fascinating. It is an invaluable work for the student, and will serve to form for him the best groundwork for future studies in this particularly useful department of science.

THE PHYSICIAN'S DAILY POCKET RECORD, COMPRISING A VISITING LIST, DIARY, AND DAY-BOOK OF ACCOUNTS; RECORDS OF OBSTETRIC PRACTICE; VACCINATIONS, DEATHS; SPECIAL MEMORANDA, ETC., ETC. Also a List of New Remedies; a Classified List of Medicines, their doses and marked value. Poisons and their Antidotes; Medicinal Weights and Measures. Fee-tables, etc., etc. By S. W. BUTLER, M.D. Philadelphia: Published at the office of the *Medical and Surgical Reporter*, 115 South Seventh street, 1867.

THE aim of Dr. Butler has been to make this a convenient and serviceable record for his professional brethren, and he has, in our opinion, succeeded in so doing. The work is small, got up in handsome pocket-book style, is compact, and the divisions have been made by one who has had ample opportunity for learning the wants of practitioners. The list of new remedies has evidently been prepared with great care, which may also be said to be the case with the doses of those medicines in common use. The poisons and their antidotes are treated in a very convenient tabulated form, and can be consulted satisfactorily in almost any emergency. The table of fees which he has introduced, is an important and interesting feature, and will no doubt commend itself, with slight exceptions, to general adoption. Although calculated for thirty-five patients daily, it can be made to serve for more by simply turning the leaf and writing on the next page, the writer not being hindered from so doing by each day of the week having a date. This plan is a wise one, as the physician can commence his book at any time of the year, and write in the date for himself as occasion may require. Facing each visiting list is a page for daily memoranda, the use of which every physician can well appreciate, as well as the index in the latter part of the work. The obstetric record is the most complete we have seen in a work of the sort; and with care in filling out, it can be made to serve as a reliable statistical account of that department of practice. Altogether, it is an admirable little work, and reflects credit upon the enterprise of the author.

Reports of Societies.

NEW YORK MEDICAL JOURNAL ASSOCIATION.

STATED REUNION, JAN. 25, 1867.

DR. ISAAC E. TAYLOR, in the Chair.

THE VALUE OF SYME'S AMPUTATION AT THE ANKLE-JOINT IN THE ADAPTATION OF AN ARTIFICIAL FOOT.

DR. E. D. HUDSON, according to previous arrangement, remarked upon the above subject. He said: No amputation of the inferior extremity can ever compare, in its value to the subject, with that of the ankle-joint originated by Mr. Syme. Twelve years of experience with that variety of operation have afforded me assurance that it is "a fact complete," not capable of being improved in its general character. It is scientific, practically of the utmost use, and subservient to the best interests and happiness of the patient.

Mr. Fergusson avowed that he "knew of no kind or style of amputation which deserved more high consideration; and so far as the subject is concerned, it is one of the greatest improvements in modern surgery." No other operation has resulted so beneficially and satisfactorily. The subjects of such an amputation scarcely realize their loss, with legitimate appliance. They appear every way whole. The sensations of the stump are normal; the articular surface and thickened tissues are accustomed to the hardest service, and to bear the heaviest burdens, which, with apparatus, enables the patient to engage in his accustomed walks and vocations with unabated naturalness and endurance. One gentleman, for whom he had applied a foot, had walked thirty-five miles in a day, on a hunting excursion, while his companions did not suspect that he was otherwise than whole. So beneficent have been the results of this operation, as to have induced many a sufferer from congenital malformations, varieties of talipes, and troublesome Chopart operations, to demand it as an "amputation of convenience."

He claimed that as an operation it had for its support the soundest principle of surgical economy, since it retains, in addition to the entire length of leg, nature's foundation,—the articular portion of the shaft of a long bone,—as a base of support.

Again, its accustomed service is concurrent and coequal with that of the calcaneum, to sustain the weight and forces of the body which are reflected to it. So also to remove the calcaneum, and to substitute the articular base of the tibia, is merely a change of place, not of functions.

A cogent reason in support of amputation of the ankle-joint is, that to the compacted hardened tissue of the lower termination of the tibia are transferred and united, for a cushion, the thickened tissues which have effectually served to protect the os calcis.

The place of those tissues is changed; their accustomed function is unchanged and normal.

When the change of base and healthy union of the hard and soft parts are successfully perfected, the same condition and serviceableness of the end of the stump is gained as that of the natural heel. After a very short period of exercise the sensations become perfectly natural, and the end of the stump as enduring as the heel of the natural foot.

He had been led to a very great interest and persistent advocacy of Mr. Syme's method, by a regard for the humane principles of rational conservatism, and by the numerous cases of ankle-joint amputations which had demonstrated to him the superior utility of that operation to any amputation of the leg, or any modification of the general one of Mr. Syme. Of fifty recent cases which had come to his hands for final treatment by mechanical means, not one had failed of a highly gratifying success. Both patients and surgeons who have witnessed their results, have been every way pleased with their exceeding benefit. Not every subject is in immediate condition for the adaptation of apparatus, for reasons that will readily be apparent to every surgeon.

Some require treatment for ulcerations, thickened tissues, swellings, and tenderness; others require some inuring treatment, before the application of apparatus. In no instance did he venture to apply apparatus until the patient could endure the end of the stump upon either the bare floor or some unyielding support with ease.

Those leg-makers who have only stereotyped apparatus to apply indiscriminately for amputations in the continuity of the leg, and who find this new method incompatible with their highest ideas, had, to his personal knowledge, treated such cases by apparatus, as for amputation. This allows no weight at the end of the stump, but distributes it upon the walls of the leg, beneath the head of the tibia, and up around the thigh.

Those who have no discriminating knowledge of surgical operations, nor of physiological, anatomical, and pathological principles, can hardly be expected to appreciate and sustain an amputation of the ankle-joint; nor can they treat it legitimately with apparatus which fulfils the design of such an operation.

To illustrate: Captain ——, who had suffered an amputation of the ankle-joint—Syme method—came to this city and applied to —— —— for apparatus. He was informed that, because of a slight prickling sensation when he rested his stump on the floor, it should not receive any weight at its end. An artificial leg was applied, as in ordinary cases of leg amputation, to take the weight of the body upon its walls and the thigh, so as to suspend and relieve the end of the stump. The captain entertained the plea of tenderness as valid; but being very greatly annoyed by the weight and irritation of the apparatus, he sent for a surgeon of this city, who, upon examining the stump and appliance, immediately transferred him to Dr. H. He found his stump admirably well formed and healthy, except a little prickling sensation, which hard pressure induced.

After ten days of preliminary treatment, during which a casement and foot were fitted, and trials made, the prickling had entirely subsided, the natural sensation of the heel was restored, and the patient went out walking without inconvenience.

The sensation of prickling is no unusual complaint for persons to make who have suffered an injury of the tissues of the heel or foot, when they have so far recovered as to begin to exercise the part. It is a mere temporary sensation, which exercise soon converts into a normal one. The objections to Syme's operation, tenderness, unsoundness, and unreliableness as a basis of support, after the stump has become well healed, are entirely gratuitous.

The practice of Mr. Syme (original method) to exsect the indurated tissue, the most depending and most serviceable feature of the tibia, thereby exposing the cancellated structure, and also to remove the malleoli through their base on a level with its articular surface, is unphilosophical and inexpedient. The increased vascularity of the cancelli must necessarily conduce to protract the tenderness of the face of the stump. Some surgeons strive to enlarge the base of support afforded by the tibio-tarsal surface, by sawing the malleoli off,

at a line transverse with the end of the tibia; but the practice is entirely gratuitous, and in some respects prejudicial.

The inter-malleolar space is the only true and all-sufficient base of support; any additional surface is superfluous and increasing the periphery of the end renders it unduly large for the adaptation of symmetrical apparatus. The articular surface should not be molested. The malleoli should be exsected with the saw, at a bevelling angle of some forty degrees. The most serviceable and best proportioned stump is thus composed. With the dense ivory structure, the cancellated and medullary tissues all preserved, other matters being equal, we may rationally anticipate the best results. The modified variety of Baudens, the dorsal flap, or that of Roux, lateral flap, will never be chosen varieties, but adopted as a *dernier ressort* only. Even when the operation is thus modified, the stump is eminently superior for utility, and the entire pressure upon its face, to any amputation of the leg.

He had had two cases of the bilateral-flaps variety, made for want of plantar tissue, and cicatrized over the end of the stump, and one of the dorsal variety, upon each of which the patients bore their entire weight, on an artificial foot, with the utmost comfort.

The compensative apparatus, he had been the first to originate and apply in the United States; nor was he aware of any like legitimate treatment abroad.

With it he had invariably made the face of the stump the basis of entire support, and with no intervening substance, other than one or two thicknesses of soft flannel cloth. The apparatus is composed of a light semi-cylindrical wooden case for the leg, receiving the bulbous end of the stump in a concavity, at its lower end, fitted snugly to the posterior half of the parietes of the stump and leg for two-thirds of its length, while its base is entirely supported. Wide leather bands lace up over the anterior half of the leg, to keep it in situ.

The case is strengthened with strong hickory pins, so dovetailed as to prevent its splitting or yielding to the weight of the body. To the leg and stump-case an artificial foot, of natural size and shape, is attached by a strong ginglymus ankle-joint, on a line nearly parallel with that of its mate. An artificial Tendo-Achillis passes up from the heel, through an inclosed groove into the calf of the casement, where it is strongly inserted. It preserves the foot at a right angle with the leg part, when the weight of the body passes over and forward upon the ball and toe-piece of the foot. The latter is made to hug the ground, the same as the toes of the natural foot, by a strong lever and rubber spring. When the heel strikes the ground, the anterior part of the foot is depressed, but elevated sufficiently by rubber flexor springs, when the weight is off, to prevent tripping. The apparatus is covered with green rawhide, dried and contracted on, and coated with a neat flesh-colored enamel. It may be dressed with stocking, shoe, or boot, at pleasure, the same as its fellow.

With its application the patient is, to all appearance and for usefulness, restored to a normal condition.

The great and important feature of the Syme operation at the ankle-joint, he would repeat, is the natural, philosophical basis of support which the method retains, and the opportunity it affords, by a sufficient shortness, for the adaptation of a compensating artificial foot, and a ginglymus ankle-joint in a proper place.

The main and defensive feature of M. Pirigoff's modification is the increased length of stump, created by the excision of the tibia and calcaneum, and the annexation of a greater or less portion of the latter to the former, for the service of the "*poor man*," with the application of a "bucket" or "boot."

Every physiological anatomist must readily perceive that the increased length of the stump, by an adventitious portion of the os-calcis, will, in the ratio of its increased length, necessarily impair it for the application of legitimate mechanical appliance.

Statistics furnish abundant evidence that it possesses no superior advantage as relates to mortality, sloughings, necrosis, or other untoward events, over the Syme method; *nor even as a reliable basis of support;* only to secure the benefits of an *os-peg-leg*—the similitude of the wooden relic of barbarity.

The special interests of the subject, of an amputation of the inferior extremity, are the matters of importance —"and how the patient may *most fitly* use the rest of his life, by walking on an artificial leg." No artificial leg has been, or can be constructed and adapted to any stump of the leg, having its parietes for support, with such perfect favor, as that which he originated and adapts for ankle-joint amputations. The same apparatus, modified, may be applied to the Pirigoff modification, but the result is far less satisfactory.

There is one condition of the ankle-joint in which the Pirigoff method may be adopted to the very great benefit of the patient, viz. Where caries, necrosis, or injury of the tarsal end of the tibia, precludes the possibility of the Syme method, and would render the Pirigoff method a valuable alternative to an amputation of the leg at its lower third. In any such event, to excise the diseased tibia, and a sufficient amount of the calcaneum, and annex to the tibia to compensate its loss by excision, would be an additional fact to surgical improvement—a worthy expedient—but only as an alternative to the leg amputation. It would make the leg of normal length, and alike serviceable as a Syme case for the adaptation of a befitting apparatus.

Dr. H. condemned the indifference of those surgeons who operated without reference to the adaptability of the stump for the most comfortable contrivances, and gave the instance of a lady now wearing a clumsy apparatus upon whom the surgeon performed an amputation at the upper instead of the lower third, because she was then a poor girl and could afford only a "*peg-leg.*"

After a few remarks by Dr. Hamilton in continuation, the Association adjourned.

NEW YORK ACADEMY OF MEDICINE.

STATED MEETING, March 6, 1867.

DR. ALFRED C. POST, President, in the Chair.

DR. ANDERSON delivered to the Academy several volumes, transmitted to him as its late President. Among these was a copy of the Transactions of the Montpelier (France) Academy of Medicine.

DR. UNDERHILL moved that the latter institution be placed upon the exchange list of the Academy, and that the present donation be accepted, with thanks.—(Carried.)

DR. ANDERSON also reported, that in accordance with the wish of the Publication Committee, a sufficient number of Dr. Post's Eulogy upon the late Dr. Valentine Mott had been furnished to the different medical schools of the city, for distribution to the graduates of the season, of which courteous acknowledgments had been returned.

SPECIMENS OF AMERICAN ANTIQUITIES.

DR. JOHN C. DRAPER presented to the notice of the Academy a specimen of common salt, nearly chemically pure, which was discovered by the insurgents of the late war upon the *Petit Anse* island, near Vermilion Bay, Louisiana. The deposit was found some fifteen

feet below the surface, and appears at that depth to be pretty generally distributed over the island, which is some five thousand acres in extent. Upon the surface of this deposit were found the bones of the American elephant, and beneath both was discovered a neatly woven mat, composed of the common Southern cane (*Arundinaria macrospermum*). The original of the photograph now exhibited by him was presented by J. F. Clues, Esq., to the Smithsonian Institution, Washington, and is in a state of excellent preservation, owing to both the strongly silicious character of the cane itself and to the properties of the soil from which it had been removed.

This specimen was of interest, as throwing some light upon the antiquity of man; it at least proved that he existed previous to the period to which the skeleton of the elephant in question belonged.

The Academy then adjourned.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

CONVERSATIONAL MEETING, JAN. 9, 1867.

PRESIDENT, DR. WM. MAYBURRY, IN THE CHAIR.

DISCUSSION ON DYSTOCIA.

DR. WM. B. ATKINSON opened the discussion by reading a paper, of which we give the following abstract:

Under the head of difficult labor may properly be considered all cases where, from any cause, the delivery is retarded or rendered dangerous. These may be of two classes:—preventable and unavoidable. The patient may neglect the evacuations, and delay ensue from a distended bladder or rectum. The physician may not be in attendance sufficiently early to rectify a malposition which could have been corrected if detected in time. External manipulation would be here indicated and valuable.

The unavoidable cases are much more numerous and varied. The os uteri may delay by its obstinacy, or the pelvic outlet be almost completely excluded by a variety of causes. The duty of the accoucheur is to be vigilant and neglect no precautions. The bladder and rectum should be emptied; neglect in this particular may induce paralysis or rupture of these organs, fistula, rupture of the uterus, etc. Cases of delay were cited as illustrative of this point.

Where the os uteri does not yield readily, we may bleed, nauseate, use belladonna to the parts, but above all, employ anæsthetics.

Opiates, etc., may be employed when the labor is tedious, thus quieting the contractions and giving time for the circular fibres to dilate. These are contra-indicated in full labor. Perhaps nothing is of so much value as anæsthesia to incomplete insensibility. Eutocia by this means should always be obtained when no objective symptoms are present. Tincture of gelsemin has been recommended to procure painless and speedy dilatation of the uterine mouth. Great benefit may be derived from the aid to dilatation afforded by the finger of the obstetrician hooked in the anterior lip, with gentle and firm traction made forwards and downwards; this prevents the cap or sling forming over the fœtal head, thus acting as a cause of delay, and also rectifies these malpositions of the os so frequently productive of tedious labor, the result of so-called obliquity of the uterus. On this point much might be said, and many cases were quoted to prove the value of this procedure.

The membranes should not be ruptured too early, lest we thus produce tedious labor, nor should they be allowed to remain too long intact. On both these points the speaker descanted at some length to enforce his views, and show the importance of attention to these particulars.

When, after the evacuation of the amniotic fluid, the pains cease, or occur at long intervals, they may be renewed by sweeping the finger around within the os at frequent intervals.

The decubitus of the patient often causes a change in the pains and retards or accelerates delivery. A change from the side to the back, or the opposite side, will frequently improve the contractions, and cause the head to come down more rapidly.

In slow dilatation of the os it is suggested to divide to a limited extent a portion of the circular fibres, and it is claimed that the operation is very frequently successful and very serviceable. Objected to as dangerous and rendering the patient liable to rupture of the uterus. The same has been done with the perineum. Both are strongly advocated by high authority, but are of doubtful propriety. These points ought to elicit free discussion as important if safe, highly dangerous unless experience has taught otherwise.

When are ergot or the forceps to be employed? The former is indicated when the os is freely dilated or easy of dilation, when no obstacles but want of pains interfere to delay the delivery. If the patient is exhausted, combine it with stimulants. The speaker had never met with any bad results from the employment of this remedy. He preferred the fluid-extract as more convenient, and more suitable, for a variety of reasons.

Finally, the forceps come in play as an efficient aid. Here, the physician requires judgment and patience to determine how early they should be employed. They should be regarded as aids for the benefit of the mother or child, and not for the convenience of the doctor. When the delivery is delayed by exhaustion, *inertia uteri*, or failure of the pains from any cause; when further delay is dangerous, and there are fears for the life of either the mother or child; for these, and other or similar cogent reasons, we may employ this instrument. He did not regard their use as fraught with the danger attributed to them by many. He rather felt that many of the fistulæ, etc., attributed to their employment, were the effects of pressure from the child's head, rather than pressure or other action of the forceps.

Some remarks followed on other obstetric operations. Craniotomy, etc., the gimlet craniotome of Dr. Harlow was eulogized as the most perfect and safe instrument for the purpose yet devised.

In conclusion, allusion was made to the general conduct of the obstetrician, his art requiring skill, gentleness and firmness; and yielding an ample reward when properly followed.

DR. HAMILTON remarked that one important point in reference to facilitating the passage of the child's head had not been alluded to in the paper of Dr. Atkinson; that is, to act on the lower portion of the vagina—introducing one or two fingers between the head of the child and the wall of the vagina, and, at the moment of a pain coming on, to press firmly, letting the fingers perform this office on the perineum in the direction of the anus. It seems to have some effect on the passage of the child's head, as it descends and presses in that direction, the motion takes place rapidly.

With regard to the period at which the membranes should be broken, he was undecided. He has sometimes ruptured very tough membranes when the child's head followed rapidly; under other circumstances, this interference was followed by no advantage, and sometimes it was absolutely disadvantageous from loss of the wedge-like bag. As to forceps, he ac-

knowledged their value, but feared they were instruments of great abuse.

Dr. Hatfield requested some remarks from Dr. Harlow as to the advantages of his instrument to which the reader of the paper had referred;

And Dr. Harlow, first speaking of the subject-matter of the paper, believed that we may avoid extremes in using the forceps. His rule is, to be governed by considerations of safety to the mother and to the child, regarding not only their lives, but their well-being also. If by delay we compromise the well-being of either in any way, we are guilty in not using the forceps; if, on the other hand, we use them for our own convenience, and thus compromise either, we are guilty; it must not be used as a time-saving instrument.

With regard to his instrument for entering the fœtal head, he believed it to be the best of the kind which can be used. It has been noticed by Prof. Hodge, who says that it may be used for breaking up the face, and the base of the skull. It is also mentioned in Braithwaite that it may be used where the ossification is greater than usual and other instruments cannot be employed readily. It is not to be employed except when absolutely necessary. He was led to its invention by having a case of contracted pelvis where he was obliged to operate on two or three occasions; the diameter of the superior strait was not more than two inches and a half; he had introduced Meigs' perforator, and found that after inserting it into the skull, he could not insert the forceps that accompany Meigs' perforator. On his way home he contrived this instrument. It consists of an olive-shaped, gimlet-like screw, enlarging rapidly from its point to its broad base; the edges of the screw are entirely smooth, and on entering the parts, there is no probability of wounding the mother. It has no sharp edge as has Smellie's scissors, and other instruments. It not only perforates the skull, but enlarges the opening sufficiently for all the purposes that are desired in craniotomy. After turning, followed by inability to deliver, it can be readily used to break up the base of the skull.

Dr. Washington F. Atlee, alluding to the like and dislike of the forceps, etc., remarked that it requires a mechanical mind to use the forceps justly for the benefit of the mother and the child; otherwise it may be injurious in the hands of those who abuse it. In a great many patients, the existence of the axis of the pelvis is lost sight of in the use of the forceps, and therefore the application of the forceps is difficult in the hands of such practitioners, when it would be perfectly easy in the hands of others. He prefers Siebold's forceps because he has long been accustomed to their use, and in an extensive range of applications, has always been able to employ them. Many physicians condemn the use of the forceps from want of mechanical skill in their application. They don't throw the handles back. There is no position of the head in the pelvis in which the forceps cannot be applied; the higher the head of the child is in the pelvis, the further back must you press the handles, sometimes even to pressing the perineum and rectum backwards to the os coccyx. Dr. Atlee prefers forceps short in the handles. He believes compression to a certain extent will not injure—and almost every case is attended with some compression—the very pressure on the handles will do this; but with short-handled forceps, with the pivot in front, it is impossible to do injury, especially with long blades, by any amount of compression which the hands can make upon the head.

There is an occlusion sometimes of the os uteri, where labor will continue for days without progress, in which by pressing the sharpened finger-nail against the circular fibres and scratching through at the time the pain is on, you perforate the closed tissues, and immediately there is a sudden expansion of the whole os uteri, and the child is born in a few minutes.

Another cause of dystocia is an excess of waters, where the head of the child blocks up the pelvis even after the purse of waters has been broken previously. A large amount of waters will have the same effect as a second child. The uterine efforts cannot be well expended on the body of the child if a large body of waters is around it, even though the purse may have been broken below the head; the head is sometimes so impacted in the superior strait that the labor is delayed by the large quantity of water above the superior strait; then pushing up forcibly the head of the child and sustaining it in this position until the waters are drawn off, will facilitate the labor. Again, in breech presentations, we find the life of the child sacrificed, especially in first labors, by the head being retained with pressure of the head against the umbilical cord, pressing it against the superior strait. Traction of the body, and turning up the body so as to follow the curve of the pelvis, sometimes fails in delivering the head; the finger in the mouth sometimes fails to deliver in time, particularly in first children; in such cases the speaker strongly recommended and always practised, pressure externally; in every foot or breech presentation he calls the nurse to the bedside and tells her to place her hands immediately over the lower part of the abdomen, and to follow his motions by strong pressure, and almost instantaneously the head is forced right out, and the child saved. This is not a procedure recommended by authors generally, but is a practice well worth following.

With regard to the instrument of Dr. Harlow, he related a case proving its value. The head had been perforated, but the brain had not been discharged; the operation had been performed with the ordinary scissors, but the incision was a linear one, and the pressure of the head in coming through the superior strait forced the bones together and kept the brain within. By making a crucial incision, delivery was effected. The instrument of Dr. Harlow would obviate this difficulty.

Dr. Andrew Nebinger mentioned several interesting cases of labor where manual dexterity assisted mechanically without resort to instruments. He exhibited the cranioclast of Prof. Simpson, designed, after removal of the contents of the cranium, to break up the bones of the skull, leaving them in contact with the scalp. The head collapsing is forced down into the cavity of the pelvis and removed by traction, with the same instrument. He referred to the statements of Dr. Tyler Smith, who says that there is no necessity for craniotomy under any circumstances, and he induces premature labor at seven or eight months.

Dr. Spooner desired to add his testimony to that of Dr. Hamilton to the assistance often given after the head of the child has passed down within the cavity of the pelvis, by the pressure on the posterior portion of the vagina by two or three fingers within the canal, which would also often stimulate the uterus when contractions were apparently failing.

As to rupturing the membranes, if the patient has the appearance of an unusually distended uterus indicating a large collection of the liquor amnii, it is often to be inferred that the uterus does not contract regularly and the labor does not progress as well as it would were it not for this distension, and therefore he generally ruptured the membranes; in general, however, and in primiparous cases as a rule, it is not indicated; in primiparous cases, because we expect there will be more or less delay as the head comes to distend the perineum, and there

will be more or less heat and congestion resulting from the dryness caused by an early rupture.

In regard to the application of the forceps, he admitted the facility with which the instrument can be applied if the person has a mechanical mind and properly appreciates the canal of the pelvis.

In craniotomy, after the evacuation of the head, he takes away the bones without the soft covering, trying to leave the soft tissues so as to protect the mother from the irregular portions of the cranium which remain projecting through the scalp tissues.

Correspondence.

OUR KNOWLEDGE OF MEDICINES.

To the Editor of the Medical Record.

Sir—Your remarks upon our want of knowledge in medicines are eminently true, and they admit of very general application. There is one point which I think bears upon this question, which you have not alluded to. Every one must admit that our appreciation of the value of medicine is at a very low ebb; but there is a something behind which too many of us are apt to lose sight of, and that is a practical knowledge of those remedies which are really useful to every practitioner. The student only learns these by rote; and it being a mere effort of memory, their physical properties, action, and doses, soon pass from his recollection. He is not brought into practical familiarity with them. The teacher of this branch thinks that he has performed his duty, when lecturing upon a given drug, to pass the specimen of the same around in a bottle, and tell all about it, and then it is dropped; there being no account made of it, except a few lines in the note-book. The lecturer on the practice of medicine, unless, as you say, he dismisses the treatment with the magic words, "whiskey, quinine, and iron," only names an extra article or two that may be used; but how it is to be employed, and in what doses, he does not generally care to state. Even if he did, what particular practical utility would it be to the student, if it is not stamped indelibly upon his mind by some other means?

Your correspondent believes that much good could be done in this connexion by writing out the prescriptions which each patient treated in the clinics is to have. This could be done on the blackboard, and would take very little time, and be of great benefit in constantly keeping before the mind the necessity of being careful and intelligent prescribers. In order to render such an exercise more impressive, there would be no impropriety in giving the reason for prescribing such and such articles, and explaining their applicability to the particular case. Every young practitioner of our day feels that his knowledge of materia medica is, from the neglect of his teachers, very deficient; and when he is called upon to prescribe for his patients, he is naturally diffident about writing the prescription which he should. His memory merely supplies him with a very few remedies to select from, and these are still further reduced in remembrance, because he does not feel sure that he knows how to write for them. The consequence is very easily seen; and, with the exception of a few that he has selected from his limited list and combined to suit himself, he has nothing to fall back on. He is virtually discouraged at the onset, in his efforts to prescribe; and not wishing to be counted an ignoramus by his apothecary, he makes himself believe that, after all, therapeutics is a good deal of a humbug, all medicines act pretty nearly alike, there is no certainty in any, and so he gets to be a man with one idea.

But a mere knowledge of the names and uses of medicines cannot make accomplished prescribers. A physician who writes a prescription should know how to compound it himself. Now, how is it possible to possess this knowledge in the present system of instruction in materia medica? The answer is a very simple one. He should at first get behind some apothecary's counter, and should learn the art of skilfully and intelligently "putting up" prescriptions. No such instruction is contemplated in our colleges, and I am sorry to say there is but little promise that it will be done, at least for a long time to come. How many physicians write for articles which they would not know if they were shown them? Suppose a mistake should be made by the apothecary, would it be likely to be detected by the physician who might have the mixture presented to him afterwards?

In conclusion, I submit if it would not be a proper plan to recommend the different teachers to write their prescriptions upon the blackboard in every case where a prescription is given, and that a dispensing department should be attached to each college sufficiently large to give each student during some part of his pupilage a sufficient chance to compound such prescriptions.

I am, sir, truly yours,

G.

New York, February 9, 1867.

ETHER VERSUS CHLOROFORM.

To the Editor of the Medical Record.

Sir—The death by chloroform which recently took place at Bellevue Hospital, gives a sad interest to the question of surgical anæsthesia. The repeated accidents which have occurred in May, 1866, in Berlin; June, 1866, in Philadelphia; February, 1867, in New York, have naturally enough staggered the faith of many surgeons in the great anæsthetic.

Allow me, sir, to refresh the minds of your readers with reference to the past records of chloroform. As early as 1853, Baudens acknowledged eighty deaths, and A. Forzet found eighty-five. In 1859, Barrier de Lyon ascertained that there had been above two hundred deaths. Diday collected from that date to 1864, twenty-one cases registered in England, leaving at least as many which were unrecorded. If there was another drug instrumental in the destruction of so many lives, would it not be ejected from the *materia medica?* True, the fault has been put on the impurity of the article employed; but how often has chloroform been used in case of accident, in its purity, as in the instance at Bellevue; showing that it need not borrow its toxic properties from heterogeneous substances. Hence, from 1847, the date of the beginning of the use of anæsthesia, surgeons have been divided into two classes, the chloroformists and the etherists; and though the first-named had, at first, the advantage, their rivals have steadily persevered, patient and unrelenting, in their efforts to demonstrate the general efficiency and the absolute safety of ether.

In 1848, Cantu remarked that half of his chloroformized frogs died, and hardly any of his etherized ones. Sedillor admits, at the same date, that when he stops giving ether, anæsthesia may continue, but in no case become aggravated. Not so with chloroform; when discontinued after insensibility is produced, its action is continued, its symptoms may in some instances cause death. This circumstance constitutes the most marked difference between the anæsthetic rivals.

The few men who supported this view against triumphant chloroformists found an early and eminent representative in T. E. Petrequin, chief-surgeon of the Hotel Dieu de Lyon. For nearly twenty years he has

banished chloroform and used ether in that hospital, the largest in France, where from fourteen to fifteen thousand patients are treated annually, and where more operations are performed than in any other. From this telling experience, Petrequin, Diday, and in fact l'Ecole de Lyon, assert that pure ether has for years accomplished in their hands, without accident, those services that chloroform has rendered elsewhere at a cost of several hundred lives. Is not this question worthy of further study? Yours, etc.,

E. Seguin, M.D.

BLEEDING FROM THE TOOTH-SOCKETS.

To the Editor of the Medical Record.

Sir:—I am reminded by the paper and discussion at a late meeting of the *East River Medical Association*, as reported in your columns, of certain foot-notes in *Chelius' System of Surgery*, by the translator, Dr. South, which may be of value to those who may not have access to the work. The subject of "hæmorrhagic diathesis" is rather fully alluded to under the heading of "bleeding from the tooth-sockets."

A case is there related of a person in whom the hæmorrhagic diathesis was very strongly developed, who bled to death after the extraction of a second molar tooth for caries in spite of the application of the following remedies: lunar caustic to the bottom of the socket, a sponge-tent soaked in a so'u'ion of sulphate of copper, followed up by careful plugging of the socket. Brodie, who had been consulted, after three applications of the actual cautery, and careful plugging as before, finally resorted on the fourth day of the hæmorrhage, which had been subdued only for short intermissions, to ligature of the common carotid artery. The wound made in the operation bled very little at first, but in the course of a few minutes after the operation it began to bleed profusely. Ice to the wound, and ice to the left side of the face, appear to have had some effect; but the hæmorrhage afterwards returned and carried off the patient (July 7, 1816), a week from the time of the removal of the tooth. Another case is related where the hæmorrhage succeeding the extraction of two teeth at different periods, was checked by the *effectual* application of the actual cautery, after failure of means which very readily suggested themselves under the circumstances. The point made by the annotator is that the heated wire, not more than a line in thickness, should be made to descend to the very bottom of the socket, and thus command the bleeding vessel, which is the proper artery of the tooth. This, Dr. South thinks, should be resorted to at once before the constitutional powers are disturbed, and before a latent phthisical tendency is developed, of which he can recall an instance. The suggestion I think a valuable one, and certainly more rational than the introduction of the wax model recommended by Cortez, or the internal use of ergot by Dr. Ryan, whose successes are to be regarded rather as coincidences than as consequences.

Yours, etc.,

* * *

Albany, N. Y., March 7, 1867.

A COMMENT UPON AN OBSCURE PASSAGE.

To the Editor of the Medical Record.

Sir:—With a full appreciation of the sly humor of your correspondent "B," who, in his note to you of the 20th Feb., ult., *vide* vol. ii., p. 23, has taken due advantage of a typographical error, I hasten with becoming alacrity to do a simple act of justice to the gentleman who has thus been made the subject of mirthful comment. "B," I fear after the manner of too many expounders, twists his text, which as printed reads: "Amaurotic symptoms upon which a diagnosis of cerebral disease was based, according to Dr. Watson, were in *no* case found to have depended in reality upon a plug in a defective tooth."

By the simple substitution of *one* for "*no*," the meaning of the speaker becomes at once comprehensible. So, too, the reporter, had he not been compelled to write against time, might have said, *had been*, instead of "*was* based;" and even besides these two errors, might never have allowed a rather grave one of construction to have escaped his eye. But "proofs" may be corrected *ad infinitum*, as you are well aware, and still have many unaccountable typographical errors left.

Hoping, in common with all commentators, for a certain share of success in the elucidation of dark passages,

I remain truly yours,

J. S.

New York, March 6, 1867.

Obituary.

PROFESSOR HOWARD TOWNSEND, M.D.,

of Albany.

At a meeting of the physicians (graduates of the Albany Medical College), resident in Schoharie and Delaware counties, held at Stamford, Delaware county, February 2, 1867, Dr. C. C. Covil, Chairman, and Dr. J. D. Havens, Secretary, the following preambles and resolutions, presented by Dr. Havens, were adopted:—

Whereas, The ways of Providence are not as our ways, but are oft mysterious and past finding out; and,

Whereas, It has pleased Divine Providence in His inscrutable wisdom to remove from us in the full vigor of manhood, in the midst of a life of activity and usefulness, our beloved friend, associate, and medical teacher, Dr. Howard Townsend, who recently filled the chair of Materia Medica and Physiology; therefore,

Resolved, That we, in common with the Faculty and Alumni of the Albany College Hospital, and other institutions, sadly feel the loss of one to whom we feel deeply indebted for much of our knowledge in his special department, which he was ever ready and anxious to impart, not only in, but out of the lecture-room. We shall ever feel a deep sense of gratitude for his unwavering solicitude for the professional advancement of those under his instructions.

Resolved, That while he was ever careful to impart the *true* and *demonstrated* principles of science, and reject the *false* and *undemonstrated* (which he regarded as bursting bubbles on the great ocean of knowledge), he kept pace with its onward march, and ably and honorably filled positions of trust in the literary and scientific world. Prof. Townsend was not only the true physician, but the literary man and scientist. By his untiring energy he did much for the advancement of true principles, true science, and true knowledge.

Resolved, That while we regret with heartfelt sorrow his early death, yet we bow with submission to the will of Him "who doeth all things well." That we will ever cherish a lively sense of gratitude as we contemplate his benevolent qualities of heart, his urbanity of disposition, his generous impulses, and the true *Christian character* which marked his life.

Resolved, That we extend to the Faculty of the College, and to the literary, scientific, and educational societies with which the deceased was connected, our sorrow for the irreparable loss they have sustained; also, our

heartfelt sympathy to the family and friends of the deceased.

Resolved, That a copy of these resolutions be presented to the family, and also be published in the Albany *Argus* and Bloomville *Mirror*.

Medical News and Items.

PERSONAL.

MEDICAL DEPARTMENT—U. S. A. APPOINTMENTS.—To be Chief Medical Purveyor, with the rank of Lieutenant-Colonel—Surgeon Richard S. Satterlee, U. S. Army, to date from July 23, 1866.

To be Assistant Medical Purveyors, with the rank of Lieutenant-Colonel, all to date from July 23, 1866—Surgeon Charles McDougal, U. S. Army; Surgeon Eugene H. Abadie, U. S. Army; Surgeon Robert Murray, U. S. Army; Surgeon Charles Sutherland, U. S. Army.

To be Surgeons, all to date from July 20, 1866—Assistant-Surgeon, Clinton Wagner, U. S. Army; Assistant Surgeon Jos. P. Wright, U. S. Army; Assistant-Surgeon Charles C. Gray, U. S. A.; Assistant-Surgeon William C. Spencer, U. S. Army.

To be Medical Store-keepers, all to date from July 20, 1866—George Wright, of Pennsylvania; George T. Beall, of New Mexico; Andrew Victor Cherbonier, of Maryland.

M. MAREY.—The celebrated author of the *Researches on Circulation*, and inventor of the Sphygmograph, Marey, has just exchanged his position of Substitute for that of Professor Suppliant to the chair of *Natural History of Organic Bodies*, in the College of France.

DR. WM. H. THOMSON, on the 7th instant, delivered a highly interesting lecture on Modern Statistics as applied to Ancient History, before the New York Historical Society.

DR. RUFUS K. BROWNE, on the same evening, discoursed on the Nervous System of Man and Animals, before the Association for the Advancement of Science and Art.

DR. WM. MANLIUS SMITH, of Manlius, Onondaga county, N. Y., desires us to state that any communications likely to add to our knowledge of the properties, etc., of Conium, would be acceptable to the above address, and that due credit in future reports will be given to the sources of such information.

DR. WILLIAM E. STILLWELL, an Alumnus of the College of Physicians and Surgeons, (class 1830), and member of the Medical Society of the County of New York, died in this city, February 6, in the 60th year of his age.

DR. SAMUEL DEMAREST, of the Northern Dispensary, died February 10, in the 29th year of his age.

DR. WM. B. LITTLE, American Consul at Panama, died of yellow fever, January 29th ult.

DEATH OF DR. HENRY BRYANT.—We are pained to hear of the death of Dr. Henry Bryant, of this city, which took place at Porto Rico on the first instant. Dr. Bryant was passing the winter in the West Indies in the pursuit of health, and in the collection of objects of natural history. He was an enthusiastic ornithologist, and to his liberality the Boston Society of Natural History is indebted for the recent donation of the magnificent La Fresnaye collection of birds. No particulars concerning his death have been as yet received.—*Boston Medical and Surgical Journal.*

AMERICAN MEDICAL ASSOCIATION.—The Eighteenth Annual Meeting of the American Medical Association will be held in Cincinnati, on Tuesday, May 7, 1867, at 11 o'clock A.M.

The following Committees are expected to report:—On Quarantine, Dr. Wilson Jewell, Pa., Chairman; On Ligature of Subclavian Artery, Dr. Willard Parker, N. Y., Chairman; On Progress of Medical Science, Dr. Jerome C. Smith, N. Y., Chairman; On the Comparative Value of Life in City and Country, Dr. Edward Jarvis, Mass., Chairman; On Drainage and Sewerage of Cities, etc., Dr. Wilson Jewell, Pa., Chairman; On the Use of Plaster of Paris in Surgery, Dr. Jas. L. Little, N. Y., Chairman; On Prize Essays, Dr. F. Donaldson, Md., Chairman; On Medical Education, Dr. S. D. Gross, Pa., Chairman; On Medical Literature, Dr. A. C. Post, N. Y., Chairman; On Instruction in Medical Colleges, Dr. Nathan S. Davis, Ill., Chairman; On Rank of Medical Men in the Army, Dr. D. H. Storer, Mass., Chairman; On Rank of Medical Men in the Navy, Dr. W. M. Wood, U.S.N., Chairman; On Insanity, Dr. Isaac Ray, R. I., Chairman; On American Medical Necrology, Dr. C. C. Cox, Md., Chairman; On the Causes of Epidemics, Dr. Thomas Antisell, D. C., Chairman; On Compulsory Vaccination, Dr. A. N. Bell, N. Y., Chairman; On Leakage of Gas-Pipes, Dr. J. C. Draper, N. Y., Chairman; On Alcohol and its Relations to Man, Dr. J. R. W. Dunbar, Md., Chairman; On the Various Surgical Operations for the Relief of Defective Vision, Dr. M. A. Pallen, Mo, Chairman; On Local Anæsthesia, Dr. E. Krackowizer, N. Y., Chairman; On the Influence upon Vision of the Abnormal Conditions of the Muscular Apparatus of the Eye, Dr. H. D. Noyes, N. Y., Chairman; On the Comparative Merits of the Different Operations for the Extraction of Vesical Calculi, Dr. B. I. Raphael, N. Y., Chairman; On the Therapeutics of Inhalation, Dr. J. Solis Cohen, Pa., Chairman; On the Deleterious Articles used in Dentistry, Dr. Augustus Mason, Mass., Chairman; On Medical Ethics, Dr. Worthington Hooker, Conn., Chairman; On the Climatology and Epidemics of Maine, Dr. J. C. Weston; of New Hampshire, Dr. P. A. Stackpole; of Vermont, Dr. J. Henry Janes; of Massachusetts, Dr. Alfred C. Garratt; of Rhode Island, Dr. C. W. Parsons; of Connecticut, B. H. Catlin; of New York, Dr. E. M. Chapman; of New Jersey, Dr. Ezra M. Hunt; of Pennsylvania, Dr. D. F. Condie; of Delaware, Dr. —— Wood; of Maryland, Dr. O. S. Mahon; of Georgia, Dr. Juriah Harriss; of Missouri, Dr. Geo. Engelman; of Alabama, Dr. R. Miller; of Texas, Dr. Greensville Dowell; of Illinois, Dr. R. C. Hamil; of Indiana, Dr. J. F. Hibberd; of the District of Columbia, Dr. T. Antisell; of Iowa, Dr. J. W. H Baker; of Michigan, Dr. Abm. Sager; of Ohio, Dr. J. W. Russell.

Secretaries of all medical organizations are requested to forward lists of their Delegates as soon as elected, to the Permanent Secretary,

W. B. ATKINSON, M.D.
215 Spruce st,
Philadelphia, Pa.

MEDICAL EDUCATION OF WOMEN IN EUROPE AND AMERICA.—A small audience gathered on the evening of the 28th ult., at the Hall of the N. Y. Historical Society, to listen to a lecture by Dr. Elizabeth Blackwell, entitled "The Medical Education of Women in Europe and America."

Previous to the commencement of the lecture RICHARD H. BROWNE, Esq., made a few remarks with reference to the history and workings of the New York Infirmary for Women and Children during the past thirteen years. The lecturer of the evening, he added, would speak in support of the Hospital College for Women, recently chartered by the State Legislature, and which it is hoped will soon be in successful operation in this city.

DR. ELIZABETH BLACKWELL then said, substantially: While travelling in Europe last summer, she had observed, with great interest, the increasing attention which was being paid to the subject of female medical education. She found that this idea of giving to women a wider knowledge of medicine than has ever been attempted before, is no longer an entirely new subject, as it was in Europe sixteen years ago. It is a subject of ridicule to some, of doubt to more, of decided approbation to a few; but whatever the feeling with which it is regarded, it is no longer ignored. Full credit or blame is attached to America for having originated this bold experiment of doctorship, and the leading medical journals of England uneasily assure their readers from time to time, that this foolish American humbug is quite exploded. Nevertheless, the lady-doctor is taking root even in England. The interest of the work there clusters around Miss ELIZABETH GARRETT, who has won a legal footing in the profession as Licentiate of the Apothecaries' Hall, and who has been for some time established as a medical practitioner in London. The French Medical School of Algiers has also admitted a lady student to its classes, offering her the same education and the same diploma that it gives to its male students. Such instances of the admission of women into medical schools have never occurred before; it is entirely a new experiment, directly due to the influence of American example. Some time ago, the Emperor of Russia gave a distinct commission to Dr. H. DE HAWROWITZ, who was sent over to inquire into the sanitary condition of our armies, to report also upon what part women were taking in medicine. This special commission grew out of the application of twenty-five Russian ladies for admission into the medical schools of St. Petersburgh; and as Russia did not want to lead in an innovation, she sent to see what America was doing. Last year, a commission from the Swedish government visited England for a similar purpose, fifteen young ladies having applied for the privilege of entering the medical college of Stockholm. Thus, in the most enlightened nations of Europe attention has been called to this new idea of giving to women the complete education of the physician; and though no institution has yet been formed for providing this higher education (the old schools of midwives being still the only system of instruction), yet, if the experiment succeed in this country, it will undoubtely be followed abroad. The speaker then urged, at great length, the necessity of united effort and liberal assistance in founding in this, the Metropolis of the New World, a college worthy of our people, in which females who desired to do so might gain, through a proper course of study and practice, a thorough knowledge of the science of medicine.

At the close of the lecture, which was listened to with unbroken interest, the financial report of the Hospital College, in prospect, was read by R. B. MINTURN, Esq. The paper set forth that the College had received its charter from the State Legislature, but that in order to carry out its provisions $100,000 were needed. Of this amount $25,000 had already been subscribed, and it was hoped that the deficiency, though large, would soon be made good. A number of subscriptions were then offered by persons in the hall, after which the audience dispersed.

THE THIRD ANNUAL REUNION OF THE O. Æ. SOCIETY, BELLEVUE HOSPITAL MEDICAL COLLEGE, took place on

the evening of February 25th, in the lecture-room of the institution. The auditorium was filled by a large assemblage of students and friends, male and female. Dr. George R. Kent presided, who, in a neat address, inaugurated the anniversary exercises, which included an essay, "The Healing Art," by J. W. Read, of New York; a poem, by J. Russ Evans, of Ohio; an address to the students and graduates, by Prof. George T. Elliott, M.D., and responses to the following regular toasts:—Bellevue Hospital Medical College, the Faculty, Alumni and members of the O. Æ. Society, and the Ladies, by Dr. James R. Wood, Dr. Frank H. Hamilton, Dr. Charles A. Lee, and Dr. Louis A. Sayre. The intellectual entertainment was agreeably interspersed with instrumental selections from standard operas, which pleasingly varied the proceedings. At the annual election of the Society the following gentlemen were chosen as officers for the ensuing year:—Ed. C. Harwood, of Vermont, President; William Sprague, of New York, Vice-President; C. G. Stedman, of Ohio, Secretary, and J. W. Bowden, of New York, Treasurer.

The Annual Commencement of the Medical Department of the New York University came off, March 1, in the chapel of the institution. There was a large attendance on the occasion, with an interesting and handsomely carried out programme. The valedictory address, which was short and suggestive, was delivered by Professor John C. Draper, who congratulated the graduates upon the completion of their college course, and pictured the duties that devolved upon them, and the honor that perhaps awaited many of them in the exercise of the most honorable of all the learned professions. Eight prizes were awarded for distinguished progress in their studies to as many students. A social supper closed the Commencement exercises.

The Annual Commencement of Bellevue Hospital Medical College was held at Steinway Hall, on the 28th ult. Prof. Isaac E. Taylor, President of the College, conferred the degree of M.D. upon 140 graduates, of whom forty-four were from New York, and the remainder containing representatives from nearly every State in the Union, including Georgia, Mississippi, Louisiana, and Virginia.

After the degrees had been conferred, the address to the graduates was delivered by John G. Saxe, Esq., the poet and humorist. Being in one of his happiest moods, he sent forth a vast fund of common sense, concerning "doctors and patients," his thoughts at times being clothed in the most grotesque garbs. The valedictory, by F. B. McNeal, M.D., of the graduating class, and a most artistic rendition by the orchestra of Bosquet's "Nightingale Polka," closed the exercises of the evening.

Long Island College Hospital.—The regular term of lectures in the Collegiate Department of the Long Island College Hospital, was commenced March 2. Darwin G. Eaton, M.D., Professor of Chemistry and Toxicology, was introduced by Dr. T. L. Mason, President of the Collegiate Department, and delivered a very interesting lecture on motion, heat, etc., making several experiments in the way of illustration. To show the force of gravitation he drew a five-pound weight to the ceiling, a height of sixteen feet, letting it fall to the floor. This weight, before reaching the floor, he said, was going with double the speed it was when it started, showing that it was at the rate of thirty-two feet per second. This was precisely the rate of speed of all motion, for should this weight continue falling, it would not fall faster than thirty-two feet per second. He held that the motion was not destroyed by the striking of the weight upon the ground. If he had a delicate thermometer he would show that the weight had become heated by the motion. Heat was therefore obtained from motion; and to illustrate this he struck a copper wire several times with a hammer, producing heat enough to light alcohol. Fire might be produced in three different ways—by percussion, friction, and compression, and he gave illustrations in each. He spoke of the motion of the earth and said that, according to the calculation of Dr. Meyer, if the world should come in contact with another body, the concussion would be sufficient to set fire to and burn fourteen such worlds.

The First Annual Commencement of the New York College of Dentistry was held at Steinway Hall, March 6. The Degree of D.D.S. was conferred upon nine graduates, and speeches were delivered by Dr. Eleazar Parmly, President Board Trustees; His Hon. Mayor Hoffman, and Professor Frank H. Hamilton.

Alumni Association, University Medical College.—After several informal meetings, an organization of a Society of the Alumni of the Medical Department of the University of the City of New York, was completed on Friday evening, March 6, in the council-room of the University. The following officers were elected: Dr. Samuel S. Purple, of N. Y., President, class of 1844; Dr. J. B. M'Cann, of Virginia, class of 1843; Dr. Solomon Satchwell, of N. C., class of 1845; Dr. Daniel Ayres, of Brooklyn, class of 1845; Dr. Henry S. Hewit, class of 1847; Dr. James R. Leaming, of N. Y., class of 1849; Dr. Frederick D. Lente, of Cold Spring, class of 1849, Vice-Presidents; Dr. H. Mortimer Brush, 1862, Secretary; Dr. George K. Smith, of Brooklyn, 1859, Treasurer; Dr. H. M. Sprague, of West Farms, 1861, College Historian; Dr. George T. Elliot, Orator. Councillors, comprising one from each class, were also elected, as well as a Committee of Nominations and Arrangements. It was voted that a meeting be held in October, when the address of Dr. Elliot is to be delivered, and an alumni supper given. There was a large attendance of the alumni residents in N. Y. and vicinity.

Bellevue Medical College—Alumni Association.—A meeting of graduates of the Bellevue Hospital Medical College was held at the college lecture-room, on the 28th ult., by adjournment from a similar meeting on the 26th, for the purpose of taking preliminary steps towards the organization of an association of the alumni; Dr. L. M. Yale in the chair. A committee, appointed at the previous meeting, presented a partial report upon a form of organization, which was recommitted with instructions to report in full at a general meeting of the alumni of the college, to be held at the same place on the evening of Thursday, 28th March, at eight o'clock.

Post-Partum Hæmorrhage arrested by Ether Spray Externally.—Dr. Braxton Hicks (*Lancet*) reports a case of the successful application of the ether spray to post-partum hæmorrhage. The usual remedies were at first resorted to, and failed; but the nebulizer caused the uterus instantly to contract, and so it remained.

Cholera in Durham.—The townships of Coxhoe and Quarrington (near Durham) have lately been visited with cholera. Both these villages suffered severely during the epidemic in 1849. The sanitary authorities are exercising every precaution against its spread.

Errata.—Page eleven, first column, sixth line from bottom of page, for *Loibrich* read *Liebreich*; for *sectore*, fifth line, read *rectus*; fourth line, for *ends* read *end*. Second column, fourth line from top, for *sücklayering* read *rücklagerung*; eighth line, for *tenotome* read *tenotomy*.

Original Communications.

DESCRIPTION OF

AN IMPROVED EXTENSION APPARATUS

FOR THE TREATMENT OF

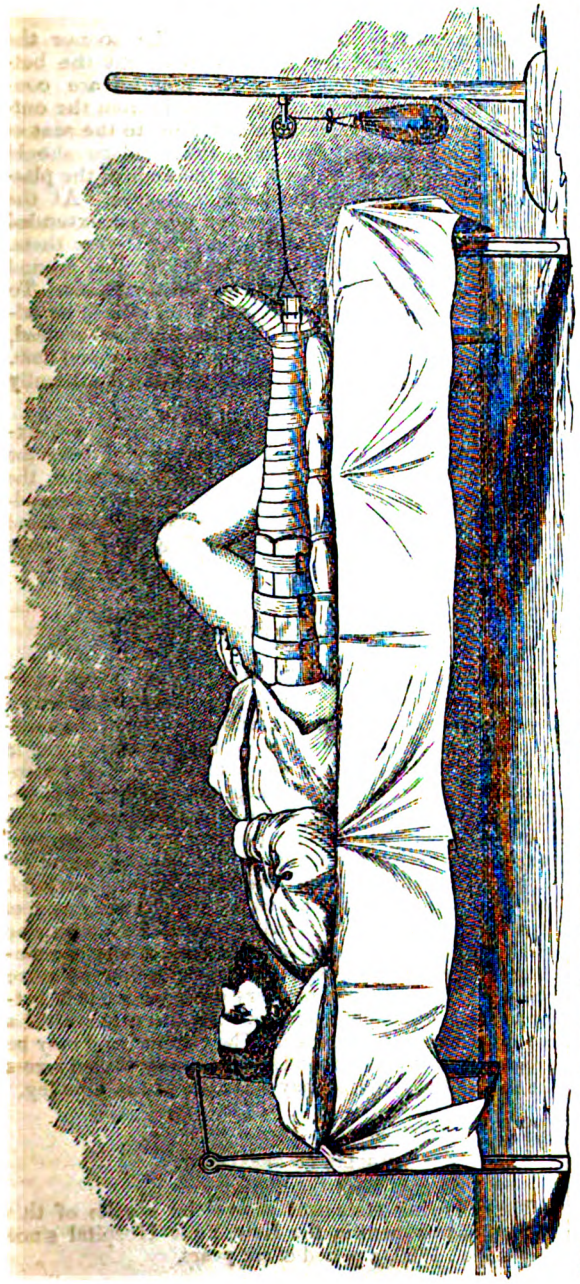
FRACTURE OF THE THIGH,

IN USE IN THE NEW YORK HOSPITAL FOR THE PAST SIX YEARS, AND IN THE UNITED STATES ARMY GENERAL HOSPITALS DURING THE CIVIL WAR.

INTRODUCED BY

GURDON BUCK, M.D.,

SURGEON TO THE NEW YORK HOSPITAL, ST. LUKE'S HOSPITAL, ETC., ETC.



ARTICLES COMPOSING THE APPARATUS.

Fig. II.—Two bands of adhesive plaster spread on Canton flannel or thick twilled cotton; each band being two inches and a half wide and two feet long. At the end of one of the bands, a piece of elastic rubber webbing, *a*, two inches wide and ten long, is attached. At one end of the other band, a buckle, *b*, of corresponding width, is fastened.

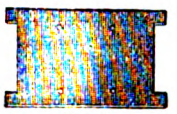


FIG. 3.

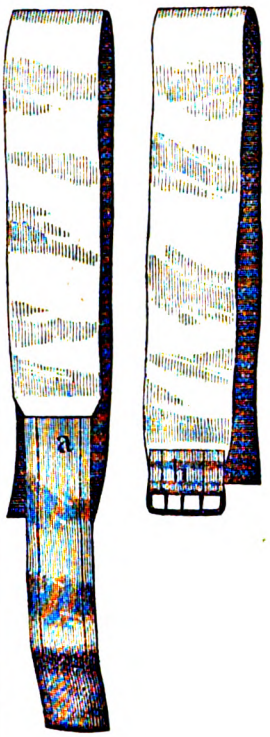

FIG. 2.

FIG. 4.

Fig. III.—A thin block of wood three inches and a half wide transversely, and three inches vertically.

A PERINEAL BAND FOR COUNTER-EXTENSION.

Fig. IV.—*a*, The perineal portion consists of rubber tubing of one inch calibre, having inside of it a tube of muslin stuffed with bran, and left an inch longer than the rubber tube at both ends. At each end of the muslin tube, a metallic ring is first fastened, and then shoved within the rubber tube, to the end of which it is also fastened. This arrangement preserves the rubber tube from being over-stretched.

b b, Two straps fastened to the rings at the ends of the perineal portion, serve to lengthen it and allow it to be made fast to the head of the bedstead.

c, A belt that passes around the opposite side of the body, and maintains the bearing of the perineal band in a line with the axis of the body and limb. The perineal portion should be wound with a narrow strip of Canton flannel or other soft material, and this should be changed as often as soiled.

Fig. V.—Four guttered coaptation splints, covered with flannel, are intended to surround the fracture and be secured in place by three elastic bands, each having a buckle at one end.

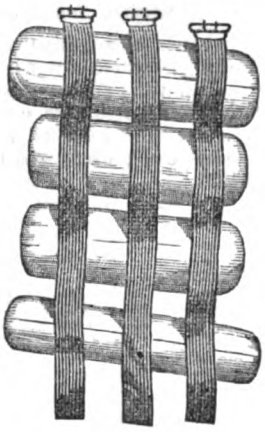

Fig. 5.

Fig. VI.—An upright supporting a pulley wheel *a*, to be fastened to the floor by three screws, opposite the foot of the bed.

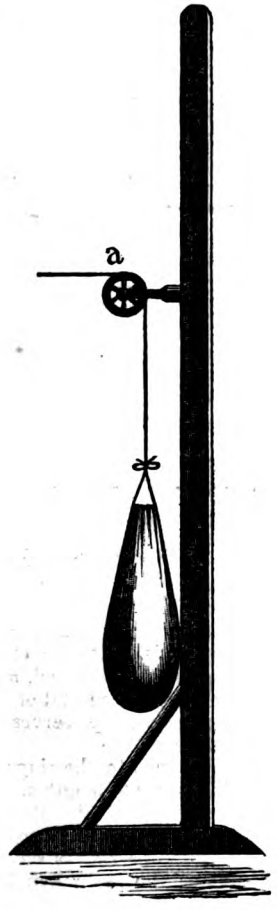

Fig. 6.

MODE OF APPLICATION.

The bands of adhesive plaster are first to be applied, one on either side of the limb from a point above the ankle upwards as high as the seat of fracture. The limb is then to be bandaged in the usual manner, beginning at the toes and covering the plasters, but leaving their lower ends free. The band of elastic webbing is next passed round the sole of the foot and fastened to the buckle on the other side of the foot. The block of wood should then be interposed between the loop of webbing and the foot. A cord fastened to the block thus adjusted is passed over the pulley, and has a weight suspended from it. This arrangement combines elasticity with the extending force, keeps the bands stretched out smooth, and prevents pressure upon the ankles. The amount of weight required must be proportioned to the resistance to be overcome, and the toleration of the patient. Sometimes five or six pounds only can be borne at the outset, and an increased weight subsequently.

After a fracture has taken place the sooner the limb is put up and subjected to treatment the better. Spasmodic twitchings of the muscles are controlled, and the patient made comfortable from the outset. To permit the application of lotions to the seat of injury during the first few days, the bandage should not be carried above the knee, and the ends of the plaster should be rolled up and kept in reserve. At the end of six or eight days the plasters may be extended up on the thigh, and the bandage contined over them. The coaptation splints are now to be applied around the thigh and secured by the three elastic bands. To complete the apparatus the perineal band should be adjusted and its ends fastened to the head of the bedstead, so as to be in a line with the axis of the body and limb. The limb should be raised on a hair cushion sufficiently to keep the heel from pressure.

In the employment of this method of treatment, experience has shown that in a large majority of cases the use of the perineal band may be dispensed with, the weight of the body being sufficient to resist the extending force. This resistance may be further increased by raising the foot of the bedstead five or six inches above the floor.

ADVANTAGES OF THE METHOD.

The advantages claimed for this method over others heretofore in use, are its great simplicity of arrangement, facility of management, and especially the comfort it affords the patient during a long confinement in bed. The efficiency with which uninterrupted extension of the limb can safely be kept up, secures, it is believed, better results than have been obtained by any other method. The sitting posture may be allowed without disturbing the action of the apparatus: an indulgence for which patients are always very grateful, and one which greatly alleviates the irksomeness of their condition. The materials required for employing this treatment are obtainable under almost any circumstances, the only indispensable article being adhesive plaster. If this is of the ordinary description, it is better to use it of double thickness. All the other articles requisite may be improvised. The elastic band may be dispensed with, and a round stick properly placed across the foot of the bedstead may serve instead of a pulley.

RESULTS OF TREATMENT.

The following statement shows the results of this method of treatment in the New York Hospital since September, 1860, a period of six years.

TOTAL NUMBER OF SIMPLE FRACTURES OF SHAFT OF OS FEMORIS TREATED. 146 CASES, AGED FROM 2 YEARS TO 63 YEARS.

Under 15 *years of age*, 54 *cases, of which* 45 *male*, 9 *female.*

Primitive Shortening in 46 of 54 cases.	Weight employed in 38 cases.	Result of Treatment in the 54 cases.
⅛ inch to 2⅜ inches. Average 1⅛ inches.	3 pounds to 20 pounds. Average not quite 9 pounds.	No Shortening in 38 cases. Maximum of Shortening, 1 inch in 2 cases. Average of total 54 cases, about 1-6 inches.

Over 15 *years of age*, 92 *cases, of which* 79 *male*, 13 *female.*

Primitive Shortening in 83 of 92 cases.	Weight employed in 79 cases.	Result of Treatment in 89 cases recorded.
⅛ inch to 3⅜ inches. Average 1⅜ inches.	3 pounds to 28 pounds. Average 14½ pounds.	No Shortening in 12 cases. Maximum of Shortening. 1½ inches in 2 cases. Average scarcely ⅛ inch.

In all cases the measurement was taken with a graduated tape from the anterior superior spinous process of the ilium, to the extremity of the internal malleolus.

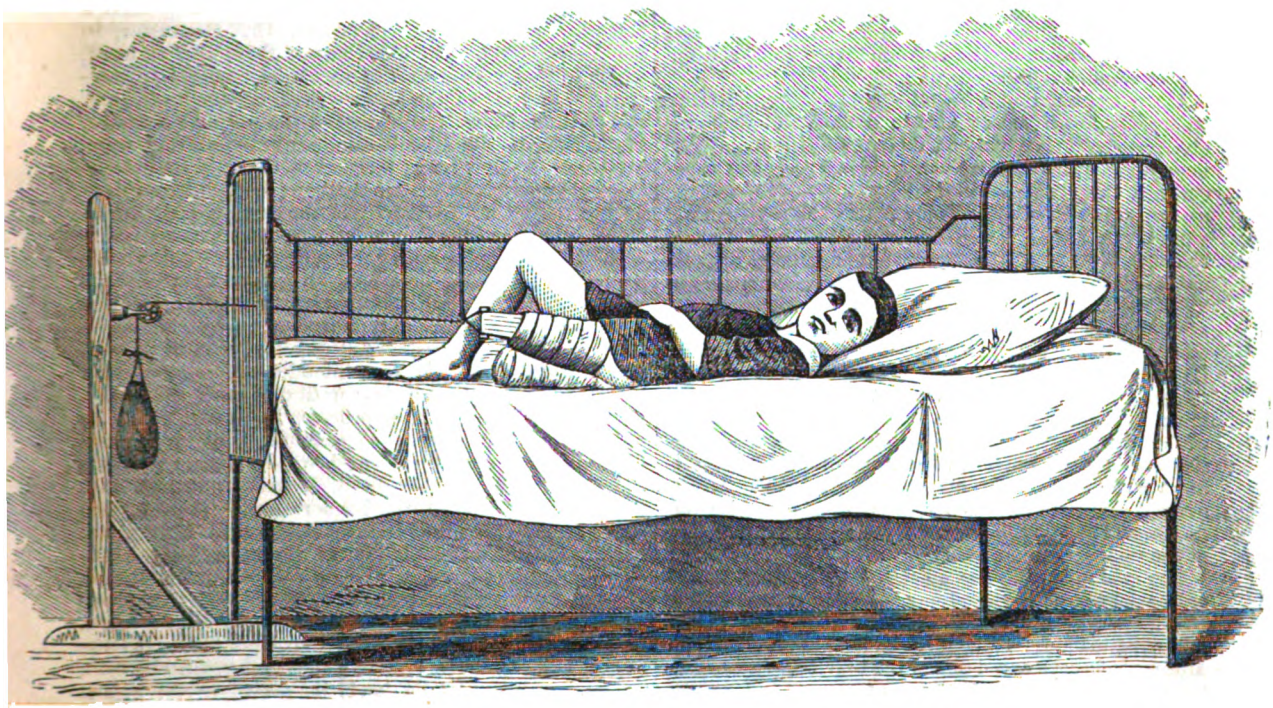
The employment of a weight and pulley, for the purpose of maintaining constant extension of the limb in the treatment of morbus coxarius, was first brought to the notice of the medical profession in New York by Henry G. Davis, M.D., and to this source the author acknowledges his indebtedness for the suggestion of its application to the treatment of fracture of the thigh.

APPLICATION OF THE METHOD TO STUMPS.

Another important application of the weight and pulley extension has been made by A. Hermance Smith, M.D., Assistant Surgeon U. S. Army, to the treatment of stumps of the lower limb, in which retraction of the soft parts leaves the end of the bone exposed, and sometimes necessitates re-amputation. It was first employed by Dr. Smith in the U. S. Army General Hospital at Frederick, Maryland, in September, 1862.

Subsequently, Assistant-Surgeon Robt. F. Weir, M.D., in charge of the same hospital, extended its use to the treatment of stumps immediately after amputation to prevent painful twitchings, and found it afforded great comfort to the patient, and that without interfering with the application of the requisite dressings to the stump.

It has since been extensively employed in civil as well as military practice, and its superiority established as the best means we possess of preventing retraction.



CAUSE OF CHOLERA.—Dr. Klob has, with the use of a microscope of from eight hundred to a thousand magnifying power, discovered in the rice-water evacuations, millions of microscopic fungi, which, in appearance, differ little from the ordinary European forms; and that they form the basis of the frightful malady, and that cholera is easily propagated by their means, can scarcely any longer be doubted.

THE HIGHEST POINT INHABITED.—The highest inhabited place upon the face of the globe is a farm-house situated 13,500 feet above the level of the sea, or about two miles and a half above the level. This lofty and elevated habitation is situated near the highest peaks of the Andes in South America, Chimborazo, which rises to 21,449 feet above the level of the sea.—*Exchange.*

CASES OF SUB-MUCOUS FIBROID TUMORS OF THE UTERUS.

By WM. WARREN GREENE, M.D.,

PROFESSOR OF SURGERY IN BERKSHIRE MEDICAL COLLEGE, AND IN THE MEDICAL SCHOOL OF MAINE.

In the autumn of 1864, I was consulted by Mrs. —— of Hampden co., aged 53. She was not married until after the termination of her menstrual life, which ceased eleven years ago. About eight years ago, she began to suffer from pain and sensations of weakness and dragging through the pelvis, accompanied by occasional slight hæmorrhages. Within the last three years there had been a marked aggravation of all these symptoms, especially of the hæmorrhage, which for the year past had amounted to alarming floodings, several of which attacks had nearly proved fatal, and from the effects of one of which she did not have time to rally before another occurred.

She was now extremely anæmic and debilitated, and her mind anxious and depressed.

She had been under the care of several physicians, all of whom had pronounced her disease the "*turn of life.*" One had made a vaginal examination and pronounced the uterus healthy.

When will physicians learn, and through their lady patients, that a woman with *healthy uterus and ovaries* passes out of her menstrual life as safely as she enters it? It is a burning shame that this term should be used as often as it is, to cover professional ignorance or carelessness, and thousands of poor, suffering women be physically ruined, simply from the want of an intelligent examination of the reproductive organs, and the proper treatment thereof.

Upon examination, I found the uterus considerably enlarged, smooth and regular in outline, and the neck obliterated. There was no dilatation of the *os*. The impression everywhere given to the finger, and especially in the posterior *cul-de-sac* of the vagina, and *per rectum*, was that of a firm body within the cavity of the womb. A sound passed five and a half inches along the *anterior* wall of the uterus, but if curved, it could not be rotated in the cavity. The impression conveyed by it was that of a firm mass occupying the posterior and upper portion of the cavity. I now commenced the dilatation of the *os* with sponge-tents. I was obliged to do this slowly, as the process caused her much pain and nausea. At the end of a week it was completed, and with my hand in the vagina I could examine the cavity of the uterus digitally. Just within the *os* on the posterior wall was felt a tumor, regular in outline and imparting a yielding semi-elastic feeling to the finger. It was evident that there was something more above this; but its size and location prevented a satisfactory exploration of the upper portion of the cavity.

The patient was now etherized and placed in the ordinary position for lithotomy. With the assistance of Drs. Smith, Brewster, and Paddock, I operated in the following manner: Having seized the posterior lip with Museux's forceps and dragged the organ downwards as far as practicable, the instrument was placed in the hands of an assistant, and with a long-handled, probe-pointed bistoury I divided the mucous membrane over the surface of the tumor, which I then with the fingers and lithotomyscope enucleated and removed. It appeared to be a soft fibroid, and was so tender as to break into many fragments during its removal. A firm mass could now be felt above, and the mucous membrane was incised from the fundus downwards. With the scoop and handle of the bistoury, the tumor was so far uncovered as to enable me to seize it with a large pair of lithotomy forceps and turn it from its bed. It was too large to pass through the *os*, and was, therefore, divided into two parts and removed. It was a firm fibrous tumor, presenting the lobulated condition which so often obtains in fibroids of the parotid region. The hæmorrhage during the operation was considerable, although not alarming. After the uterine cavity was cleared, it soon ceased without any interference. The shock to the system was severe; for several hours the pulse was very feeble, surface and extremities cold, and the respiration sighing. By the following morning, however, reaction was fairly established; and under the influence of anodynes *pro re natâ*, twenty-three drops of the muriated tincture of iron every four hours, a nourishing diet, and frequent vaginal injections of warm chlorinated solutions, she recovered without a bad symptom. In three weeks she was able to return home. In the following spring she called upon me, on her way to Iowa to visit some friends, a strong, healthy, happy woman, having had no return of hæmorrhage or pain.

Case II.—Mrs. ——, aged fifty, was married when twenty-eight; never was pregnant; ceased menstruating when forty; always enjoyed good health until the spring of 1863, when she began to suffer from pain through the lower portion of the abdomen and pelvis, associated with occasional discharges of blood from the vagina. These hæmorrhages gradually increased in amount and frequency, as did the pain in severity, until she became anæmic and much debilitated, being obliged to assume the recumbent posture the greater part of the time. It was during an attack of flooding that I first saw her with her physician, Dr. Brewster, in September, 1865. The blood flowed from the os uteri, which to the eye and touch presented a natural appearance. The body of the organ was slightly retroflected, and its posterior wall, with that of the upper portion of the cervix, enlarged and firm, and unyielding upon pressure. At first I was inclined to think this inflammatory hypertrophy and induration; but, upon introducing the sound, the cavity of the uterus seemed to be slightly encroached upon at a point corresponding with the external swelling. I was now satisfied that we had to deal with some morbid growth in the walls of the uterus, but whether benign or malignant was not clear. To control the hæmorrhage, and at the same time open the *os* for further examination, a sponge-tent was inserted, which it was intended to follow with larger ones of graduated sizes, until thorough dilatation was accomplished. The process, however, was so painful, and her debility so extreme, that we were obliged to wait until her strength was built up, relying in the meantime upon injections of Monsel's solution into the cavity to control the hæmorrhage. This in full strength controlled the bleeding for the time being, and gave very little pain. If diluted to any extent, however, it produced severe uterine *tormina*. Tr. iodine undiluted was used several times, but it did not prove sufficiently styptic, although it gave very little pain. In about three months we were enabled to dilate the *os* satisfactorily. The patient was placed upon the back exposed to a good light, and the posterior lip seized with tenaculum forceps and the organ dragged well down into the vagina. I was now enabled to carry the finger within the womb above the point of swelling, which, from this examination conjointly with a rectal exploration with the forefinger of the opposite hand, evidently arose from a small fibroid imbedded in the uterine tissue. The mucous membrane over the tumor was abraded, and blood oozed from its surface. Having introduced a Sims speculum, I incised the mucous membrane with a scalpel. The tumor, however, was covered

by a layer of uterine fibres, which were divided; and after a tedious dissection, performed principally with the handle of the scalpel, a scoop, and the fingers, the tumor, about the size of a pullet's egg, was removed.

The principal difficulty attending the operation arose from the intimate blending of the growth with the surrounding parts. So close was this that, of necessity, some shreds of the normal structure were removed during the operation, and fragments of the tumor left behind, which were afterwards thrown off as sloughs. There was considerable hæmorrhage, which was controlled by persulphate of iron. No anæsthetic was used, and the patient bore the operation very well. She was kept quiet in bed; anodynes given *pro re natâ*; tr. ferri murias, twenty drops every four hours, and a bland nutritious diet ordered; vagina to be washed twice a day with chlorinated lotions. For several weeks there was considerable sanguineo-purulent discharge, and after this had ceased she had for three or four months occasional *slight* hæmorrhages, giving rise to a suspicion that other growths of a similar nature might exist higher up in the cavity. A careful examination, however, revealed nothing, and it was hoped that the bleeding proceeded from the site of the ablated tumor, cicatrization not being complete. Tr. iodine was injected repeatedly, and eight months ago she had the last appearance of blood. Three weeks since she called at my office and reported herself in perfect health, a statement which her general appearance fully corroborated.

In this connexion I would say that I have repeatedly used injections of liq. ferri persulph. and tr. iod. undiluted into the womb, and have never encountered any serious results. In another patient of Dr. Brewster's from whose *cervix uteri* we removed a fibroid, and with whom I had much to do, we repeatedly made these injections with but little subsequent disturbance, while a solution of moderate strength of iodine gave excessive pain.

Case III.—Oct. 1st, 1864, was called to see Mrs. T., of Madison co., N. Y., in consultation with the late Prof. Timothy Childs, M.D. For two years and a half she had been suffering from pelvic and abdominal pain, accompanied by frequent and oftentimes alarming uterine hæmorrhages. Eighteen months before she noticed a firm tumor of considerable size in the hypogastrium, which had gradually increased until now she was as large as a woman seven months pregnant. The diagnosis of several physicians who had previously examined her, was ovarian tumor. The fact, however, that the tumor was hard, a regular ovoid in shape, occupying the median line, resembling precisely a gravid uterus; and that, *per vaginam*, the feel was that of a child's head within the uterine cavity, and also that Simpson's sound was not long enough, even when the handle was carried clear to the *os*, to reach the fundus, the instrument hugging closely the anterior wall, and not admitting of rotation of curve; proved that we had an intra-uterine tumor situated upon the posterior wall of the organ. That it was sessile, was evident from the fact that at no point could a sound be passed behind it.

As Prof. Childs left for New York at this time, the patient came into my hands for treatment. For the purpose of a more thorough examination, I dilated the *os* with sponge-tents sufficiently to enable me to touch with the tip of the finger the lower portion of the tumor. The parts were very rigid, and the process of dilatation a very tedious one. The sensation imparted to the finger and through the sound was that of a soft fibroid growth, and I made a crucial incision in the lower portion and inserted pledgets of lint saturated with glycerole of perchloride of iron, with the hope of producing a slough. In this, however, I was disappointed, and I repeated the tents, determined, if possible, to produce more complete dilatation, and then to repeat the incision more extensively. For this purpose I had some very large tents made of *thoroughly* compressed sponge, changing them every two days, until the *os* was satisfactorily opened. I visited her one morning with the intention of again incising the mass, when, on removing the tent, I found attached to it a little irregularly shaped mass as large as a filbert, which I judged to be a portion of the tumor, and which my friend and partner, Dr. Paddock, found on microscopic examination, to possess the structure of a soft fibroid. It now occurred to me that possibly with tents of large size carried far up between the anterior uterine wall and the tumor, a sufficient amount of pressure might be produced to destroy enough of the mass to insure the sloughing of the remainder; it being well known that the vitality of these growths is so low, that if any considerable portion be destroyed, destruction of the balance soon follows. Accordingly I selected the largest sponges I could find, from which Mr. Geo. Meade, of this place, made me some tents, varying in length from four to six inches. One of these I pushed *entirely within* the uterine cavity, a loop of tape to which it was *firmly* attached hanging from the *os*. For twelve hours subsequently she experienced very severe pain, like the throes of ordinary labor; the tent was retained, however, till the next day, when it was removed and a larger one introduced. Upon the removal of the sixth tent, it was followed by several small fragments of the tumor, and upon thoroughly rinsing the uterus with warm water, the discharged fluid was loaded with little particles of the same. From this time the process of destruction went on. There was a constant, and oftentimes profuse, offensive discharge, loaded with particles, shreds, and lumps of the tumor, occasionally a mass as large as a hen's egg being thrown off, for the ready expulsion of which it was occasionally necessary to dilate the contracting *os*; and sometimes a larger mass detaching, which I crushed with forceps to facilitate its exit from the cavity. This process occupied fully four months for its completion, during which time, it is hardly necessary to say that the patient's sufferings were extreme, and her situation oftentimes very critical. She had by inheritance, however, a fine, elastic constitution, and in addition to a high degree of intelligence, possessed an unusual amount of moral courage.

The uterus and vagina were thoroughly washed twice a day with warm solutions of compound solution of bromine, tr. ferri murias, in twenty to forty drop doses three or four times daily, stimulants and anodynes *pro re natâ*, and a full nutritious diet given. She has had no hæmorrhage since June, 1865. The following September I made a careful examination and found the process of uterine involution to have advanced considerably. No discharges. Had regained her color, and to a considerable degree her flesh and strength. Made another examination one year ago to-day. Uterus much smaller than in September. Had had no discharge, and expressed herself as feeling perfectly well. Last April she moved to Illinois with her family, where she now resides in perfect health. I hear from her almost every week through her numerous friends who reside here, to one of whom she wrote a fortnight since, "I am perfectly well."

Pittsfield, Mass.

Public Urinals.—A bill is to be introduced into the New York Legislature establishing public urinals in the city of New York.

A CASE OF
INTERNAL ADMINISTRATION OF CHLOROFORM FOR SUICIDAL PURPOSES.

DEATH ON THE EIGHTH DAY FROM ACUTE GASTRITIS; POST-MORTEM EXAMINATION; WITH OTHER CASES.

By O. D. POMEROY, M.D.

Mrs. D., aged forty-five, on Sunday, Dec. 19, at half past one P. M., swallowed from five to nine fluid drachms of chloroform, in an undiluted state, for the purpose of self-destruction. At the time she was just recovering from a drunken debauch, to which she was occasionally subject. Physicians were immediately sent for, but none could be obtained until half-past four P. M., when Dr. Stout came.

He found the patient in a state of profound coma, extremities cold, pulse about 70, and feeble. Death seemed so imminent that no effort was made to counteract the effects of the poison.

From the attendants I learned that the chloroform produced sleep in a very few minutes; the exact time I could not determine.

At seven P.M., Dr. S. saw the patient again; she had somewhat reacted, but it was still impossible to arouse her. The extremities were now warm, pulse about 80, and pretty full. At ten P.M. she recovered consciousness, would speak if spoken to, but seemed disinclined to notice things. An intense burning pain at the epigastrium was from this time until death a constant symptom.

A bowl of strong coffee was administered, which produced no sensible effect. A movement of the bowels, somewhat resembling coffee-grounds, now occurred. Vomiting commenced soon after, and continued with varying intervals until the termination. The attendants left her at twelve, midnight, and did not see her again until next morning; she then said she had not slept during the night, but seemed drowsy, and occasionally would sleep for a few minutes. This condition of things, however, did not remain long, as during a greater part of the day there was no inclination to sleep. The Doctor saw the patient again on Monday morning, and diagnosticated the case as acute gastritis. The principal symptoms now were, intense pain in the epigastrium, and constant vomiting. The liquor calcis, flour and milk were administered, and a blister on the epigastrium.

There was no movement of the bowels after the one just alluded to.

The patient complained of a hacking cough; respiration somewhat impeded—the mind clear.

At no time was she inclined to take nourishment, as she had never relented in her desire and determination to die.

On *Tuesday*, five grains of calomel were laid dry on the tongue, but were returned by vomiting as soon as swallowed; at the same time beef-tea was given per anum, which was passed almost immediately—condition of things not materially changed.

Wednesday, as the result of a consultation, a pill containing two grains of calomel and one-eighth of a grain of morphine was given once in four hours, until three were taken; milk punch was also administered, but was soon rejected by vomiting—respiration a little worse, pain in the stomach less.

On *Thursday*, the vomiting was less frequent; there was no sleep, other symptoms remaining as before, except a jaundiced condition of the skin and eyes, which gradually increased until death.

Friday, dosed at intervals, although was easily aroused; no nourishment was taken, as it would be retained by neither the stomach nor bowels. There was vomiting of blood, evidently from the stomach, of a dark-colored matter and partially coagulated.

On *Saturday*, Dr. S. saw the patient with another medical gentleman, when an enema of quinine, brandy, morphine, and beef-tea, was given, which was instantly rejected. There was some vomiting of blood, but less than on the previous day.

Sunday, she drank a glass of milk, and eat a little bread and milk, being the only nourishment retained from the first. The physician in attendance did nothing, as the case seemed hopeless. There was no vomiting, but most of the remaining symptoms were intensified, especially the tendency to coma, and the dyspnœa. She gradually sank and died at half-past twelve A.M. The amount of blood thrown up was a little more than half a pint. The mucous membrane of the tongue, mouth, and fauces, was eroded by the action of the chloroform.

Post-mortem examination at half-past three P.M., Monday. No external signs of disease; rigor mortis fairly marked; patient very fat, weighing nearly two hundred pounds; heart containing a moderate amount of blood and somewhat fatty; left lung imperfectly collapsed and slightly adherent to the pleura, but otherwise healthy; right lung—lower lobe—in a state of grey hepatization; other portions healthy; liver, normal size, fatty, and presenting signs of commencing cirrhosis in one of its lobes; kidneys, about normal size and a little granular; œsophagus, presented nothing worthy of observation; the stomach exhibits a pretty decided fulness of its blood-vessels, with a spot of extravasation on the inner surface of its wall, nearly an inch in diameter; its mucous membrane at this point seems to be destroyed, and undoubtedly, had the disease progressed further, a perforation of the entire wall of the stomach would have resulted. The vomited blood, and the coffee-colored passage (undoubtedly blood), very probably came from the stomach.

It seems reasonable to suppose that gastritis was the cause of death, of course superinduced by the chloroform, which seems to have acted as a corrosive poison; the narcotic effect of the drug not destroying or doing more than somewhat endangering life, the quantity taken being insufficient, as cases like the following sufficiently prove.

A soldier, aged twenty-seven, on furlough and in a state of drunkenness for several days past, seeing a bottle on a table, which he thought contained alcohol, drank off its contents, which consisted, in fact, of twelve and a half drachms of chloroform.

He was found soon after vomiting, and soon became insensible, still continuing to discharge mucosities. The pupils were enormously dilated, and his aspect was cadaveric; respiration was stertorous, the pulse 100 and feeble, and the action of the heart occasionally tumultuous. There were present utter loss of consciousness, complete resolution of the limbs, and absolute general anæsthesia.

After a short period the pulse became insensible, the respiration was arrested every now and then, and there was tracheal *râle*. Stimuli to the surface and artificial respiration were resorted to, and strong coffee infusion injected. The alarming condition continued three hours, the anæsthesia remaining complete and the pupils dilated, while occasional contraction of the limbs was observed.

An hour later, however, the pulse rallied and the skin became warmer, but anæsthesia still persisted. At the end of the sixth hour, the amelioration was very manifest, and in another hour he was carried to the hospital.

He retained no memory of what had passed, and neither convulsions nor delirium ensued, and next day he complained of little but what might be due to his excess in drinking. Reported to Medical Society of the Haut Rhin, and published in *Union Med.*, No. 127, and the *Medical Times and Gazette*, Nov. 5, 1864.

H. Pringle reports a case for James Spencer, Esq., Edinburgh, in *Braithwaite's Retrospect*, part 34, p. 295, in which two ounces of chloroform were swallowed by a female servant, aged twenty-one, in the Royal Infirmary, Edinburgh, without causing death. It is due to the physicians, however, to state that the preservation of life was undoubtedly due to the very zealous and effective treatment she was subjected to.

Her symptoms were somewhat as follows, viz. perfect unconsciousness when first observed; twenty minutes after taking the drug, there was no smell of chloroform in the breath; pupils much contracted; conjunctivæ quite insensible; pulse at first not much affected, but eventually entirely disappeared for a short period; respiration at first little to be noticed, but afterwards was reduced to two or three per minute, and for two minutes ceased altogether and the jaw fell; half an hour afterwards, however, there were signs of returning animation; the pulse gained strength; the breathing became less embarrassed. *Her breath now smelled of chloroform;* pupils widely dilated; sensibility of conjunctivæ returning; extremities recovering their warmth; consciousness slowly returning. In six hours after taking the chloroform she answered when spoken to; on the next day perfectly sensible; pulse 100, soft; respiration unembarrassed; pain in abdomen; thirst and great nausea; tongue moist and considerably swollen and painful.

For the next three or four days had pain in the bowels, and tenderness when pressed upon; some vomiting and purging (blood being passed); pulse pretty rapid, etc. On the 25th, returned to her work.

The treatment in this case was sinapisms to the extremities and to the epigastrium; stomach-pump (emetics could not be swallowed), mustard introduced into the stomach by the pump, again to be withdrawn; aromatic spirits of ammonia and brandy introduced by the same means; stimulating enemata; tongue held forwards by forceps to prevent closure of the glottis; enemata of beef-tea and brandy, often repeated; galvanism and artificial respiration.

A black draught was administered by the stomach-pump, in order to dislodge the chloroform from the bowels, which evidently succeeded. After consciousness was restored, the white of egg, mucilage, and warm milk, were administered; hot fomentations to bowels; opiate; swallowing pieces of ice occasionally; leeching the epigastrium and applying sinapisms to the spine; beef-tea by the mouth, etc.

The artificial respiration, assisted by the galvanism, seems to have done the most towards resuscitating the patient. The author is inclined to recommend ammonia, instead of alcohol, in treatment, as the latter is prone to add still further to the excess of carbon in the blood, the effect of chloroform poisoning, for it (the chloroform) seems to resemble extreme drunkenness.

The smell of chloroform in the respiration not being present, forty minutes after taking it, *and* being present when the patient commenced to rally, seems to look to its extreme rapidity of absorption, and its presence in the bowels; hence the propriety of the black draught to operate upon them. The same author speaks of the only case of the kind he ever saw, in which a man swallowed *six ounces of chloroform*, but recovered from the immediate effects of the drug by galvanism and artificial respiration, "but died in forty-eight hours, in great agony, with symptoms of acute gastritis." The poison from chloroform he compares to that of opium, but remarks that "the diminution of the frequency of the respiration was not proportionate to the amount of stupor." A case is quoted from Mr. Lowe, from the same source, in which a patient having inhaled chloroform was saved by artificial respiration, when the pulse and respiration had been arrested for *four minutes!* Another case of fatal poisoning by chloroform, with the post-mortem, is so interesting I am induced to quote; it is from Dr. W. P. Bain, Surgeon to the Poplar Hospital, reported in the *London Lancet* for June, 1859, p. 507.

The Dr. was called at 7 A.M. on 27th October, to see Mrs. D.; found her insensible, head resting on her breast, countenance of death-like paleness; mouth open, eyelids half closed, eyes turned up, pupils slightly contracted, and scarcely affected by light; pulse 84, moderately full; breathing abdominal without stertor; surface and extremities warm; total insensibility. A bottle labelled "chloroform," and found in the room, furnished the clue to the cause of the symptoms. Water injected into the stomach by the pump was soon rejected, tinged with bile; sinapisms were applied to the neck, chest, and feet; continued insensible and motionless for many hours, with the exception of periodic vomiting, which took place with difficulty; respiration being stopped for half a minute, until a prolonged stertorous inspiration would be taken, when the respiration would be resumed with its former regularity; these attacks becoming more infrequent until 1 P.M., when the eyelids would move upon irritating the eye; pulse 100. At 3, more sensible, pulse 100; forearm and fingers livid-looking, and inclined to be cold; feet warm; vomited a large quantity of bile. Six P.M.; pulse 120; answers questions; great tenderness in the epigastrium; fæces and urine passed involuntarily; *the odor of chloroform very strong in the breath.* Half past 10 P.M.; pulse 160; skin warm; no headache; thirsty, and still inclined to sleep.

Says—In consequence of trouble, she arose at 3 A.M. and mixed a wine-glassful of chloroform with an equal quantity of water and swallowed it, and retired to bed.

As the narcotic effects of the chloroform had passed off, effort was made to subdue the acute gastritis set up by its corrosive action.

Effervescing and acid drinks were given, counter-irritation, anodynes, etc., employed for a week; she exhibiting all the symptoms of acute gastritis, and dying on the eighth day.

The amount of chloroform taken was undoubtedly, from the best information obtainable, correctly stated. Thirty-six hours after taking the chloroform, the smell was perceptible in her breath.

Post-mortem, forty hours after death. I will quote only the appearances of the stomach.

"The surface *of stomach* much congested, and it was much contracted about the middle portion, forming two distinct pouches; when opened, an escape of gas, possessing a very ammoniacal smell, took place; the internal coats were highly inflamed; the rugæ of the depending portion larger than usual, and very pulpy; the mucous and muscular coats for about a circle of two inches in diameter near the cardiac orifice, were entirely eroded, the peritoneal only remaining on its surface. The surrounding parts, on the contrary, were deeply vascular; perforation had also taken place near the pylorus." "The chief points of interest in this case, are the large quantity of chloroform taken, without causing speedy death; the long time (about twelve hours) of total insensibility; the permanence of odor in the breath; and the entire absence of head symp-

toms on the recovery from the quasi-intoxication. It is not improbable but that she would have recovered had the chloroform not been taken on an empty stomach undefended from its erosive action."

Dr. Corrigan (*Braithwaite's Retrospect*, Pt. 31, p. 262) speaks of a case in the *Dublin Hospital Gazette*, Nov. 15, 1854, in which four drachms and a half of chloroform were taken by mistake, by a man just recovering from a debauch, and having delirium tremens. The result was a perfect cure of the disease, without any pain or burning at the stomach; the sleeplessness, which had been so persistent a symptom, being entirely removed by the dose.

Joliffe Tufnell, Esq., in the Dublin Hospital Gazette, February 15, 1855, p. 19, in an article "On the Use of Chloroform in Delirium Tremens," says: "I have no fear of its use internally. I have employed it to a degree that may startle those who have had not much experience of it. I have, in a case of traumatic tetanus in the City of Dublin Hospital, kept a young man, aged eighteen, under its influence for nine days and nine nights successively, during which time he took a quarter of a pint by the mouth, and a pint and a quarter were evaporated closely over the nostrils, carrying him in a state of unconsciousness through this fearful disease, and restoring him to perfect health."—*Braith. Ret.*, Pt. 21, p. 72.

The conclusion of all this, manifestly is—chloroform may be taken, even for medicinal purposes, in very large doses, without destroying life from its narcotic properties; and if care be taken not to administer it on an empty stomach, or to sufficiently dilute it with some bland vehicle, as mucilage, gruel, etc., all risk of producing gastritis by such administration is avoided. I never have heard of a case in which chloroform, taken internally, has destroyed life by its narcotic properties (vide the case before referred to in which six ounces were taken, death resulting from gastritis only).

I do not know that the gastritis requires more than general principles to guide us in its treatment. The narcotic effect of the chloroform seems to be managed best by artificial respiration, galvanism, emptying the stomach by the stomach-pump, removing the contents of the bowels (for at least two cases I have reported seem to show that the chloroform may pass soon to the bowels and remain there until absorbed, as evinced by the absence of smell from the breath a few minutes after taking the poison, and its subsequent appearance upon unloading the bowels). Ammonia seems to be preferred to alcohol as a stimulant, as it does not seem to increase the amount of carbon in the blood, as is the case with the latter; which is especially caused by chloroform poisoning.

Coffee has been used in some of the cases reported, but I do not *know* that it can be regarded as an efficient antidote to chloroform.

A New Use for Pine Wood.—Mr. Pannewitz, of Breslau, has discovered a method by which a species of flannel is made from the fibres of pine leaves, which is now exclusively used in the hospitals, prisons, and barracks of Breslau and Vienna for bed-coverings. The flannel thus made has the advantage of driving away all insects; it serves for stuffing as well as horse-hair, and costs but one-third of that article; it will make all kinds of garments, which are of great durability and comfortable warmth. The liquid from the manufactory is now used as a medicine, and the refuse of the works makes the gas by which they are lighted.—*Medical and Surgical Reporter.*

Original Lectures.

SCROFULOSIS AND TUBERCULOSIS.

BEING A LECTURE BEFORE THE CLASS OF

THE JEFFERSON MEDICAL COLLEGE.

Session 1866–7.

By S. H. DICKSON, M. D.,

PROFESSOR OF THEORY AND PRACTICE OF MEDICINE.

Part I.

I shall treat of these subjects together; for although I do not believe them to be identical, as is strongly maintained by many prominent pathologists, still at times it is almost impossible, even by abstract reasoning, to separate them. The majority of pathologists regard tuberculosis as the same thing as scrofulosis, under special circumstances and in special localities.

I think we are bound to separate them; and I think we can do this as readily as we can separate purpura from scurvy, or the various forms of typhic fever, if we fix our attention upon the prominent circumstances belonging to their history. Of scrofula, we know its mode of causation; we understand how it has gradually become so extended. Of tubercle, I believe with Williams we do not know its cause; it comes upon us under the most inexplicable conditions, under contingencies which give us no explanation. Scrofulosis is of self-development, always, necessarily; no one becomes scrofulous suddenly, no more than one becomes base suddenly (*nemo repente fit turpissimus*). Tubercles may be developed in any one of us during the progress of a typhoid fever, as reported by Bell of Glasgow and others; and any one of us may fall into consumption at once, without any preliminary warning of changes in condition and constitution, as far as we know.

So slowly is scrofula developed, however, that I do not believe that it is ever developed in one generation; I believe that preparation is made in one generation, and the development is completed in another; the fathers eat the sour grapes, and the teeth of their children are set on edge. Again, tuberculosis is not itself without deposit; we know nothing of it any more than we do of dropsy before we have the exudation or deposit, or cellular metamorphosis; it is not itself without the tubercle, whose presence is essential. Not so with struma; there is nothing special, no peculiar deposit necessary, in a scrofulous case. Therefore I warn you against adopting too readily the doctrine of the identity of scrofula and tubercle. Examine the subject for yourselves, and decide accordingly. In the admirable work of Prof. Flint of New York, to which I have often referred you during the present course of lectures, the doctrine of identity is taught. I regret it very much; but I have to differ from him entirely as to the identity of a scrofulous cervical gland and a tuberculous deposit. He speaks of the cervical gland as showing you the changes which go on in tubercle; but there is no tuberculous deposit in a cervical gland. Lloyd tells you very well the changes that occur; there is hyperæmia of the gland; it is always an inflammatory gland. Prof. Flint himself says tubercle is often deposited independently of inflammation. Now, no cervical gland ever enlarges without inflammation; it becomes sore, it becomes red, and by and by it suppurates.

Vogel and others tell you that scrofulosis, tuberculosis, and typhosis, are deposits of matter, of an exudation or metamorphosis of cells, whatever they may be, identical with each other. Vogel says they all consist of what

he calls an amorphous struma, with earthy salts, a certain amount of fat, and a certain amount of cholesterine. There is no such deposit in many seats of inflammation in scrofulous disease. That such a deposit takes place in the lung, and wherever you find tubercle, I do not doubt. In the vast majority of cases of typhoid fever, no such deposit is clearly seen; and when it occurs the patient may die, and not by tubercle. These are views that are new to myself, views I suggest for your consideration. Is there such a thing as separate typhosis? I once believed there was, but I am now inclined to change my belief, as Woodward did not find it in typho-malarial intestines. You will not find it unless there is tuberculous deposit; and this is tuberculosis itself, as much so as tuberculosis of the lung.

This subject is open for inquiry, and will enrich research. There is no appellate jurisdiction which shall force us to settle a question; we are in search of truth, and every new fact gives us a little more light. The discovery of the stereoscopic examination of objects is an important one; we see two sides of the object at once. Now we are beginning to look at all subjects stereoscopically as well as microscopically, and see two or three sides of the object at once; we have made a great step in the path of science. We have the opportunity of reading the beliefs of men of science always opposed to each other; thus we are liable to learn those truths which cannot be controverted. In investigating this subject, let it be first decided what tuberculosis is? What is it? There is the greatest difference of opinion on this subject. One writer says that it is a nucleated, another a non-nucleated corpuscle; another says it contains molecular granules, another says it has none. Microscopists of equal ability differ on this point; one tells you it consists first of grey matter which gradually degenerates into the yellow; on the other hand Robin says the grey matter is not properly tuberculous at all, but a cytoblast; while Virchow says it is a metamorphosis of a cell, and not a new growth at all! Scrofulosis is identical with what form of tubercle?—the grey? the miliary? the yellow? the fatty? the albuminous? I make these observations to show there is a real difference between the two, closely as they are allied. I have no question that tuberculous deposit is a little more likely to take place in the strumous constitution, but not a great deal more. Flint himself tells you that tubercular consumption is not of more frequent occurrence in those marked by the inflammation of the cervical glands, who have suffered from scrofula in their youth, than in those who have not suffered in this way. This cervical inflammation is one of the clearest marks of scrofulous tendency, diathesis, constitution; and yet he tells you that tubercular consumption does not occur more frequently in them than in others. Nay, you find those who believe it occurs less in subjects who have suffered from inflammation of the cervical glands. I am of this opinion. The late Dr. Parrish of this city hailed the appearance of swelling of the cervical glands as one of the means of added security in such subjects, from tubercular consumption: given the disposition, it had better take this mode of manifestation than the internal. I have lived long enough, and have had generations enough of patients under my care, to be satisfied that Dr. Parrish was right. Those who have suffered from inflammation of the cervical glands in early youth are rather less liable than those who have not, *ceteris paribus*. I am certain that the ordinary marks of inflammation about the neck, as left in the well known cicatrices, are far less frequent now than when I began the practice of my profession. I don't speak of light degrees of the disease. I have in my note-books records of many cases, and in my memory a long list of cases of inflammation of the cervical glands of great intensity, great swelling eventuating in suppuration, and which I had to open frequently. How few of you are thus marked! The same number of individuals could not have been collected forty years ago without a considerable portion with manifestations clearly enough of having had these inflammations. Now, while these cases have been diminishing in frequency, tubercular consumption has increased in frequency; and the records I have examined show that, with us at least in this country, it is a disease of progressive mortality. Look at the rates of mortality in this city. In Prof. Wood's book on Practice, in one of the earlier editions, he alleges the influence of cod-liver oil, and states that there had been a diminution of the number of cases of tuberculous consumption upon the bills of mortality, corresponding with the increase in the use of that oil. He spoke the truth. It was a coincident which is rather remarkable, and is quoted in the last edition of Aitken as a permanent fact. I have taken pains to collate the facts. The use of cod-liver oil has gone on, perhaps increased; it is now used as largely as ever, and yet the number of deaths from consumption has gone on increasing steadily. The annual mortality stated in the edition of Prof. Wood's Practice referred to, was rather less than nine hundred; last year it was more than two thousand; and thus it has been for the last four years. Look at the bills of mortality for yourselves, and you will see that there has been a steady increase of the disease. I think Bennet and others maintain that it has decreased in Great Britain. I am willing to allow this, and am glad that it has so happened; but is the identity in question to be explained by this subsidence of consumption? Scrofula, they say, has also diminished. Aitken affirms that this is due to the influence of vaccination. Small-pox was a great developer of the scrofulous diathetis; and this being nearly broken down by vaccination, scrofula has become less prominent in a corresponding degree in that country. If this be true, I am very glad of it; and it does appear to be true. It also appears to be true that in the meanwhile there has not been a very great diminution, but still some diminution in the cases of consumption. I do not think this diminution is really greater than can be accounted for as a result of the nicer discrimination in diagnosis made at the present day with the use of the stethoscope and other careful means of physical exploration. Phthisis is now put under one head, bronchitis under another, and other affections of the lungs under their appropriate heads; different affections all classed formerly under the general head of consumption. So far as I can infer, really looking for the truth, all the difference in favor of our brethren in Great Britain may be accounted for in this way. Nevertheless, what I am saying to you is intended to be suggestive, rather than dogmatic. I don't wish to instil opinions in those who hear me. I desire you to think for yourselves; it is responsibility enough for me to bring before you what I think is true, without endeavoring to indoctrinate you with my own views.

Tubercular consumption is the greatest outlet of human life. If connected with scrofula as effect of cause, it is of the greatest importance to remove the cause, to remove the predisposition, which will extend; and among the causes pathologists generally hold scrofula to be. I will not deny that degree of connexion, though I deny their identity.

The investigation of scrofula affords us one of those remarkably instructive methods of study in which we take a course opposite to that generally pursued in examining disease; and instead of deriving general or constitutional disease from some local change of the

same kind continuing, we are obliged to refer the local changes to some general or obscure condition of constitution which we call scrofulous diathesis, the occult state of causation we call struma; when it manifests itself in any particular way, it is usually with some modification of inflammation, and we call this scrofula.

No organ seems to be free from this diathesis; whether it is in the blood or in the harder tissues, is obscure. I do not think we are ready for this question as yet; it is impossible to say whether the existence of the *materies morbi* in the blood has been proved undoubtedly. Coleman transferred scrofulous blood from a diseased animal to a healthy one, and the healthy animal became scrofulous. He took animals of different orders—the horse and ass—and found the disease transmissible by the blood. Tuberculosis is equally inoculable. Klenke, and later Lebert of Breslau, and Villemin, have been successful in inoculating with the tubercular matter from consumption to the lower animals, and from one animal to another; the disease being propagable both by the blood and by the deposit. In all these cases of occult diathesis, as in gout, carcinoma in scrofula, it may be a very important matter to know, and we shall know by and by, whether the original germ is transferred in the solid or the fluid form; whether it is the blood that circulates which conveys the disease, or whether it is the solid tissues which help to form and modify the blood. Probably both are concerned.

In the young child born of parents who have transmitted to it this peculiarity, we find that the very first movement of life will be marked by changes of condition. We have in Mr. Lloyd's Museum in London, two fœtuses with tubercles of the lungs. If this be proof of scrofulous deposition, we have the proof of development of scrofula in that form; but we find that these children are born with diseased skin, affections of the scalp. Soon the eye becomes affected, the lid especially, which is thickened and roughened. This we call scrofulosis. After a while there is rachitis, mollities ossium; this is called scrofulosis. It occurs in the children of parents who live in certain circumstances unfavorable to the proper development of animal life. As you go on, you find certain other affections; the heads of the bones swell and inflame—white swelling; the joints are swollen in this way. The child early shows, perhaps, spina bifida. I have seen a child under these circumstances with cleft palate, hare-lip, hydrocephalus, spina bifida, hypospadias, deformity of the genitals, all combined, and still the miserable little infant continued to live. The parents were scrofulous, and probably all these conditions concurred to the production of this universally morbid development of the child. This we call scrofulosis.

Of the three similar cachexiæ, typhosis, tuberculosis, and scrofulosis, we may regard typhosis as the most acute, tuberculosis as intermediate, and scrofulosis as the most chronic.

M. Jean Dollfus, a manufacturer in Paris, observing that the children of his workwomen died more rapidly than other children in the proportion of 40 per cent. to 18 per cent., came to the conclusion that it was due to compelling the attendance of the mothers at the manufactory too soon after their confinements; that thereby they were not allowed sufficient time to attend properly to their children during their early existence. He therefore allowed them to desist from labor for six weeks following confinement, instead of four weeks, as had been the rule previously, and this brought the proportionate mortality down to 25 per cent. His example has been imitated extensively throughout France, and the result has been that the mortality among the children of such operatives has been greatly diminished; still it has not been reduced below the proportion of 25 to 18 of the general mortality.

We know that manufacturing communities in England suffer variously from scrofula; we know that their children grow up rickety, scrofulous, deformed, disabled in many ways. Good says there is no difficulty in explaining the existence of scrofula under these conditions: They are not particularly well fed; they are not very well sheltered, they are not very well clothed, and they are set at labor too early. It is not long since the British Parliament enacted a bill preventing the employment of children at too tender an age. Children of six years of age were employed at labor, and still are, in spite of the bill, in certain branches of industry. We learn this state of things from many sources, for it has been made the theme of poetry, of works of fiction, novels, etc., as well as all medical works; and, indeed, we can often learn much professionally instructive from such works; we learn that they are employed even when in bad health. Read the sad tale of "Simon's Sickly Daughter," sad enough to make any one's eyes weep; poor fellow, he takes his sickly daughter on his shoulder and carries her to her work, for she, too, must add her little mite towards her own support.

Under such circumstances we can understand how all the people shall become scrofulous.

Young says the whole of Great Britain is scrofulous, and he attributes it to climate; but there is something in race too. The Chinese suffer as much from ochlesis, and in many parts of their country, as much from imperfect nutrition as the English, but we do not hear of scrofula as prominent among them. The blacks in Africa suffer variously and capriciously; sometimes from famine to a great extent. Famine, we know, pervades all India at the present moment, thousands dying weekly in Hindostan. They also suffer under all the circumstances, except climate, which in Great Britain produce universal scrofula, yet they are not so subject to it. In this country we do not suffer from ochlesis except in the cities; we do not suffer from want of clothing, food, or shelter; our children are not overworked in manufactories; our laborers live well, and are in every way in a better physical condition than the laborers of Great Britain; and yet scrofula is extensively met with among us. I have said that it has diminished much within my own knowledge; it goes on diminishing on account of the increased comforts, the better hygienic conditions which science in the service of health is providing every day; still there is scrofula among us.

Knox ascribes it to our remarkable hybridism; and thus we are led to consider another cause. Unquestionably hybrid races are very generally an improvement on the original races, but it must be congenial hybridism; there is a congenial and an uncongenial miscegenation, and certain races when they mix deteriorate as much as other races improve. We improve our breeds of cattle, horses, etc., by proper crossing, and so the human animal in its various tribes can be made to improve by an appropriate crossing; but there is a certain deterioration in the mixture of certain races which we can trace with ease. The Scotchman, healthy and hardy, perhaps the hardiest specimen of the human species, mixes very readily with the Indian on our frontiers, but it is an absolute fact that their offspring are all scrofulous and consumptive. Osceola died of consumption. He was the product of a healthy Indian woman and a Scotchman. The Ridge family had morbus coxarius and other scrofulous disorders, and finally consumption; and thus I could trace numerous instances which have come within my own immediate knowledge. I believe that hybridism between the Scotch

and Indian produces almost always a scrofulous race. Not so with the Frenchman and the Indian. The French, from the South of France at any rate, mingle with the Indian, and not badly with some of the better races of Africans; hence we have our octoroons, our quadroons, as comparatively healthy; but the mulatto is always liable to scrofula. As Nott says, he can never keep up his numbers; he will deteriorate, and especially by scrofulous degeneration. I speak from large observation, and say it deliberately, that I am ready to indorse all that he has written on this subject. The Portuguese in the island of Madeira mixed with the Indian or Malay, and the negro; the result has been a most miserable race, wretchedly degenerate in every way, and liable to scrofula. We know the degeneracy of the mingled races in Mexico, but whether they are scrofulous or not I am unable to assert; but we know as a fact that they are exceedingly degenerate, and among the common degenerations of the human race scrofula stands foremost.

Progress of Medical Science.

Cautions in Regard to Use of Sphygmograph.—Out of the facts detailed, as to the changes in the pulse-curve which are produced by physiological influences that are in daily operation, the following cautions arise as to the time at which sphygmographic observations should be taken:—

1. Sphygmographic observations must never be taken within two hours after a solid meal, like dinner; one hour after breakfast; or fifteen minutes after the ingestion of any alcoholic drink. The traces obtained during the temporary disturbance consequent upon either of these are entirely worthless as a representation of the real condition of the organs of circulation. 2. Observations must never be taken during a state of bodily fatigue from exertion. 3. Observations must not be taken when the patient is under cardiac excitement caused by muscular exercise. 4 Observations must not be taken when the patient is flushed with heat from external sources. 5. Observations must not be taken while the patient is under the influence of sudden emotional shock.—Dr. Anstie.—(*Lancet*, Feb. 9.)

Temperature of Body in Cancer.—Dr. Da Costa, of the Philadelphia *American Journal of Medical Science*, recently presented to the Pathological Society of that city a case of cancer of the stomach in which the temperature of the body was below 100° F., notwithstanding progressive and rapid wasting. Believing that this fact had a significance beyond this individual case, he remarks:—"It is known that in tubercular disease the thermometer indicates a heat much higher—a fever temperature. Shall we find it the rule, that cancerous affections show a comparatively low temperature? If so, many a doubtful differential diagnosis between cancer and tubercle of internal organs will cease to be doubtful. Dr. Da Costa has thus far four observations bearing on this point. In a case of cancer of the liver under his charge at the Pennsylvania Hospital, and which terminated fatally, the evening heat was never but a fraction above 99°; in a case of cancer of the mesenteric glands, of which the temperature was taken carefully by Dr. Edward Smith, it did not exceed 98°; in another case of internal cancer, it did not reach 100° F."

The Ligature of Veins (the Internal Jugular) not the Cause of Pyæmia.—Dr. S. W. Gross, in an article on Wounds of the Internal Jugular Vein, and their Treatment (*Amer. Jour. Med. Sci.*), thus speaks of the safety of the ligature:—

"After a very careful examination of the whole subject, I do not hesitate to state that the occurrence of pyæmia, when of traumatic origin, is due to the wound of the vessel itself, and not to the ligature; that a predisposition to the disease, or rather a peculiar morbid condition of the blood, is necessary for its development; and that when that predisposition exists, the affection may show itself whether the vein has been tied or not; in other words, when the coats of the vessel are healthy, and the condition of the blood is normal, the ligature is never the starting-point of pyæmia."

Injection of Acetic Acids in Cancerous Tumors.—The novelty of the past two months is the injection of acetic acids in the substance of cancers in order to secure their removal by absorption. The plan is brought forward by Dr. Broadbent, a physician who is thought highly of in London. It suggested itself to his mind in consequence of the known solvent powers of this acid upon cancer cells as seen under the microscope. Dr. Broadbent recommends that about forty drops of a mixture of one part of acetic acid with five or six parts of distilled water should be injected into the cancer; the point of the syringe being thrust (subcutaneously) into different parts of its substance during the operation, so that the agent is well disseminated through it. The injection is repeated at intervals, varying from five to ten days or longer according to its effects. The method is now being extensively tried, and many cases are reported in which large cancers have been completely and almost painlessly removed. Its true value can by no means be pronounced upon at present.—*Foreign Correspond. Southern Journal Medical Science.*

The Cause of Dental Caries in Married Women.—Dr. J. P. H. Brown, Augusta, Ga., remarks (*Dental Register*) upon this subject as follows: "The teeth are governed, in proportion to their vitality, by the laws of disintegration and reparation, like any other portion of the system. This explains why the teeth of many females, after marriage, decay so rapidly. They enter the marriage relation with so little life-power that, when they become pregnant, they have not sufficient vitality to appropriate to the tooth-germs of the fœtus enough of the inorganic elements from the food to form healthy dental tissue. In such cases the demands of the fœtus upon the mother for phosphate of lime, leave her osseous system in a weak condition. The teeth also furnish their quota of lime, but as their power of reparation is very feeble in comparison to the more vitalized structure of bone, they are left constitutionally depraved, and ill prepared to resist the chemical action of the vitiated secretions of the mouth. Hence it is that the offspring of such mothers have teeth of so frail a quality, that the best and most skilful operations upon them can prove of only temporary benefit."

A New Food.—Mr. Hullett calls attention to the value of Chinese sugar-grass (*Sorghum tartaricum*) as a valuable addition to our cereal crops; it bears six or eight times the quantity per acre that wheat does, makes capital bread, whilst the leaves and shoots are good for cattle.—*Lancet.*

Bronchocele treated by Strychnia.—Dr. C. Mann (*Cincinnati Journal of Medicine*) reports a cure of this affection by the administration, internally, of strychnia. This in a measure confirms the practice employed some years ago by Dr. Murner, of Dublin.

To make Beef-Tea Nutritious.—Let the cook understand that the virtue of beef-tea is to contain all the contents and flavors of lean beef in a dilute form; and its vices are to be sticky and strong, and to set in too hard a jelly when cold. When she understands this, let her take half a pound of fresh-killed beef for every pint of tea she wants, and carefully remove all fat, sinew, veins, and bone. Let it be cut up into pieces under an inch square, and set to soak for twelve hours in one-third of the water required to be made into tea. Then let it be taken out and simmered for three hours in the remaining two-thirds of the water, the quantity lost by evaporation being replaced from time to time. The boiling liquor is then to be poured on the cold liquor in which the meat was soaked. The solid meat is to be dried, pounded in a mortar, and minced so as to cut up all strings in it, and mixed with the liquid. When the beef-tea is made daily, it is convenient to use one day's boiled meat for the next day's tea, as thus it has time to dry and is easiest pounded. Some persons find it more palatable for a clove of garlic being rubbed on a spoon with which the whole is stirred.—"*The Indigestions*," *by Dr. Thomas King Chambers.*

Novel Method of dealing with Ligatures applied to Arteries.—Mr. Campbell de Morgan has been adopting of late, at the Middlesex Hospital, a plan of dealing with ligatures applied to vessels during a cutting operation, which merits notice. When the vessels have been tied, instead of following the usual custom and leaving the ligatures hanging out of the wound, Mr. de Morgan, by means of a needle, passes them through the skin close to where they are tied. They remain quite quiet, and come away without the slightest pain or trouble when their work is done. The wound consequently has nothing to irritate it, and enjoys every opportunity of healing by the first intention. The plan leaves the parts as quiet as if a compressure had been applied. There is now in the hospital a case in which Mr. Moore tried the method at Mr. de Morgan's suggestion, on Wednesday week, after removing a breast.—*Lancet.*

Ventilation for Invalids.—Dr. Thomas Inman (*London Medical Mirror*) thus alludes to home ventilation: "When speaking of airiness, I do not mean individuals to encourage draughts of cold air about their persons, nor can I recommend them to do as a medical friend of mine is said to do, viz. open the windows of the bedroom at night to get the fresh country air, which the town smoke vitiates during the day, so as to make it too impure for use. There may be differences of opinion on the subject amongst those who observe little; but amongst those who do, the belief is entertained that warm air moderately impure (as in a closed bed-room where two or more are sleeping), is less noxious to the invalid and those whose health is shaky, than is cold air and absolute purity. The purity does not counterbalance the effect of the chill."

Postural Treatment in Prolapse of the Funis.—This method, suggested by Dr. T. G. Thomas, of this city, has been favorably reported upon in England. One writer, however, objected to it, in a note to the *Medical Times and Gazette*, as being applicable only to cases occurring among the poorer classes of patients. To this objection Dr. Dyce makes a very sensible answer, and quotes the reply of Napoleon the Great to Dubois, when the life of the Empress Maria Louisa was in danger: "Forget the empress's station, and treat her as you would a soldier's wife." Dr. Dyce also ascribes the want of success of the previous writer, to the fact that the manipulations were made during a pain, whereas they should have been made in an interval. Two other successful cases are then alluded to.

Post-Mortem Appearances in the Syphilis of the Lungs and Intestines.—Man, thirty-six. Acquired a chancre about four years before death. Was especially affected with eruptions and ulcers. Had been treated with various anti-syphilitic remedies; for a great part of the time in a hospital; fifty-four ulcers from two lines to two inches long were found in the small intestine. The base of the ulcers contained black pigments. Some of them were granulated. In isolated cases radiated fibrous cicatricial formations were also seen on the black base of the ulcer. Small, tough fibrous granules were found upon the surface of the ulcer, corresponding to the serous membrane of the intestine, which, as well as the muscular coat, was found hypertrophied. The ulcers were exclusively found in the small intestine, and extended downwards to the *valvula Bauhini* (ilio-cæcal valve). The mucous membrane of the duodenum showed the marks of chronic inflammation; great vascular injection, and hypertrophic swelling. The mucous membrane of the stomach exhibited enlargement of the vessels, considerable thickening of the pylorus; there was atrophy of the margin of the liver, the parenchyma was pale. The constituent granules (*acini*) were pigmented in the centre. Spleen softened. Pleuritic effusion on the right side, with fibrinous pseudo-membranous deposit. Right lung; carnification of the lower lobe; œdema and pneumonic infiltration of the two upper lobes. A few soft nodules, about the size of a hazel-nut, of a homogeneous gelatinous nature, were found in both the œdematous and infiltrated portions, which seemed analogous to gummy tumors.—*Meshede, Virchow's Archiv.—Med. Central Zeitung.*

Ether Spray Process as an Aid to Diagnosis.—Dr. Edward Hayward, of London, recommends the use of ether spray as a means of diagnosticating tumors. The recommendation is based on one case of an obscure affection of the right hand and forearm of a married lady of forty. The symptoms were those of a neuralgic affection of the ulnar nerve, accompanied by the tingling of the hand and forearm, with contraction of the fingers supplied by that nerve, and a tenderness more or less over the region. A peculiar indefinite swelling was observed above the elbow-joint, and where the ulnar nerve rests on the inner head of the triceps muscle, and before it reaches the groove between the internal condyle of the humerus and the olecranon. There was pain on pressure, accompanied by numbness of the hand and great tingling of the fingers. It was thought that the symptoms were due to sequelæ of rheumatic disease, causing pressure. Ether spray was used to relieve pain, with great benefit; it softened the skin, the whole of the structure came under the fingers, softened like kneaded dough, and we could thus take up the tissues, inch by inch, between the fingers, and say there was no cyst and no tumor. Ether spray was continued, with painting the surface with tincture of iodine and oil. It did well.—*Med. Times and Gazette.*

New Form of Antiseptic for Local Use.—The *liquor carbonis detergens* is recommended. It is an alcoholic solution of coal-tar, containing, we presume, the carbolic, phenic, and other acids, with dark tarry matter, and differing from carbolic acid, as the liquor cinchonæ does from quinine. It readily mixes with water, forming a permanent emulsion, and in various strengths is available as a mouth wash, a gargle, an injection for fetid uterine discharges, cancer, retained placenta, etc., gonorrhœa in the female, foul ulcers, sloughing sores, and all maladies dependent in or complicated by parasitic beings, lice fungi, etc. It is also used combined with soap.—*Med. Times and Gazette.*

THE MORTALITY ATTENDING WET-NURSING.

IN the previous number we took occasion to remark upon the effect which the prevalence of criminal abortion had upon the decrease of our own people. The report upon which these remarks were in the main founded, was sufficiently full as to details to give rise to a good deal of concern among those interested in the natural growth of population. But there is another act to this grand social drama which, though not startling us with the appalling enactment of premeditated murder, is not on that account the less worthy of consideration; we refer to the prevalent and fashionable practice of nursing by proxy.

When we undertake to deplore the comparative paucity of children, we should not allow ourselves to stop here, but should put the question—What proportion of even these few little ones receive that careful nursing which they are entitled to? No one can answer this except approximately; but allowing for all extenuating circumstances, every practising physician knows full well that the present system of neglect of nurslings is frightfully prevalent. The fashionable mother now finds something else to do besides tending her offspring, and the real excuse is not so much on account of delicate health or physical incapacity, as want of time, and a disposition to shun that care and anxiety for the welfare of her infant which she should feel, as well as a desire, laudable enough in the abstract, to preserve her beauty of form and youthful face. This is one extreme; another is to be found in the mother less favored by fortune, who, nevertheless, is actuated by a desire no less deplorable—that of gain—and consents to hire out the nourishment of her own offspring to that of another. It is to these two classes principally—the one creating the demand and the other furnishing the supply—that the prevalence of wet-nursing is due.

The subject of wet-nursing, in its direct relations to the mortality of nurslings, has been lately attracting attention in the Imperial Academy of Medicine of Paris; and the discussions which have grown out of several documents presented to that body, as well as the documents themselves, have proved of value in associating the two in the light of cause and effect. The first paper was by Dr. Monot, who, in a report upon the great mortality among the new-born infants of the old province, Morbihan, maintained that such was the consequence of its young women leaving their homes and infants, to sell their milk in Paris. Dr. Brochard, who followed, charged the great mortality of the children of Normandy to the fact, that the majority were those taken from Paris to nurse.

Perhaps the paper which had the most weight and best succeeded in presenting the naked truth, was the one read before that learned body, on the 23d of October last, by the Honorable Armand Husson. This document, by the kindness of Dr. Seguin, is now before us, and invites a comment or two in respect to the bearing it may have upon the customs of our own people.

The writer begins by establishing the general mortality of French children, from one day to one year old, at one-sixth.

Thus Distributed:	Birth.	Death.	Per-centage of death.
City Population.....	249,847	45,766	18.32
Rural Population.....	672,857	121,045	17.96
Total.....	922,704	166,811	18.21.

This table shows that the mortality is less in the country at large than in towns, but only in the proportion of 0.34 per 100, owing, likely, to the number of town children sent out into the country. The same cause working on a larger scale, and conversely, shows a mortality of only 16.30 per hundred for the city of Paris, whereas the same mortality is as high as 17.98 per hundred in the surrounding country. The reason for this difference is an all-powerful one, when we learn that out of an annual registration of 53,335 births, Paris sent away the enormous number of 18,000 children to be nursed by strange mothers, these, for the most part, living close by and in a circumference of 30 miles. Again; in the arrondissement of Nogent le Rartoux, the deaths among the nurslings from Paris amount to 35 per 100, whereas for those children born on the spot it is only 22 per 100.

In order to show that this mortality—due to indifferent and careless nursing—is on the increase, he ascertained that from 1839 to 1858, the mean death-rate of the same children, from a day to a year old, was 29.71 per 100; then, from 1858 to 1864, it went up to 33.93 per 100; in 1862 it was down to 30.02 per 100, and in 1864 it increased to 40.07. It is true, that these children, furnished with nurses by the Government, were not born in the best conditions of vitality, but the conditions of their births were virtually alike every year from 1839 to 1864.

On the other hand, for the foundlings of the City of

Paris, placed and cared for by the administration, their mortality has been, from 1830 to 1858, 55.88 per 100, and was reduced gradually in 1864 to 39.26 per 100. Remarkable decrease indeed, showing a great amelioration; though presenting yet a mortality more than double the average one of the whole empire.

But this improvement, at this centre, does not hold good for the departments, where the death-rate among foundlings has been fearful, as shown in the following enumeration:

The mortality per hundred of the foundlings from one day to one year old in the departments of Loire Inférieure, was 90.50; Seine Inférieure, 87.36; Eure, 78.12; Calvados, 78.00; Aube, 70.27; Seine et Oise, 69.23; Côte d'Or, 66.46; Indre et Loire, 62.16; Mauche, 58.66.

The departments which present the greatest mortality are shown to belong to old Normandy, a country neither poor nor ignorant; and the inference is a fair one, that other causes than poverty and stupidity must combine to destroy these children. The three departments where forced labor, misery, and crime, are joined hand in hand; the Seine with Paris; the North with Lille, Roubaix, and Valenciennes; and the Rhone with Lyons; present only a mean mortality of the same children as 38.17 per 100.

In Great Britain substantially the same state of things exists, as has been shown to be the case in Paris; in fact, it is acknowledged by statisticians that all over Europe wet-nursing is a villanous scourge.

If we, in the contemplation of this subject, return to our own country, and view the cause of infant mortality in the same light and in the same manner as has been so ably done by M. Husson and others, we shall find that our large cities are not behind Paris or London in the extent to which the practice of wet-nursing is carried on. We doubt not, if the truth were told, that we should find that New York, Boston, Philadelphia, and other centres would, in proportion to population, excel any transatlantic city in the number of innocent victims sacrificed on this dreadful altar of expediency.

But it is one thing to refer to the existence of an evil, and quite another thing to suggest a remedy. The physician, however, is competent to treat this question, and to do much in his own circle of practice to prevent, by his advice, the continuance and growth of the vice. He may be the means of accomplishing a good deal, and he may not; but that is no reason why every practitioner should withhold his counsel when it may be, as in these cases it almost always is, called for. He owes a duty to the rising generation which no consideration for the peculiar views of his patients should deter him from performing.

An artificial ivory is now made in France from a paste of papier-maché and gelatine, and to which the name of Parisian marble is given. Among other things, the finest and most complicated mouldings for ceilings can be made, or capitals of columns can be constructed in any color. It is said to be hard, durable, and elastic.

Reviews.

Guide for using Medical Batteries, by A. C. Garratt, M.D., etc. Phil.: Lindsay & Blakiston.

For more than ten years the subject of electro-therapeutics has been commanding the attention of some of the ablest minds of the profession in France, in England, and in Germany. In this country this important department has been almost exclusively in the hands of charlatans or outsiders, and Dr. Garratt is one of the very few of our recognised practitioners who have accorded to it anything of the attention it deserves. For a number of years he has made a specialty of electro-therapeutics, and has gained the co-operation of the profession in Boston and vicinity. For his courage and independence in the face of doubt and ridicule, for the restless zeal with which he has prosecuted his investigations in the treatment of a great variety of diseases, for his tolerant and catholic spirit that has not spurned to receive suggestions from any and from every source—for all this he is deserving of the warmest praise. But here our commendation must cease. Unfortunately for the profession, unfortunately for the cause of electro-therapeutics, and very unfortunately for himself, Dr. Garratt has written a book that has already reached a third edition, of which this work before us professes to be a "synopsis," or "condensation." The original volume was severely, but deservedly criticised, not only for its inaccuracies of style as well as of statement, but more especially for its ponderousness. This "condensation" is an improvement upon the former work in only one respect—it is shorter. From the 1100 pages of the larger volume he has simply dropped 930, leaving most of his faults as a writer as conspicuous as before. If he could only have dropped the entire 1100 pages the improvement would have been greater still. Industry alone can never make a writer. There must needs be at least some regard for the laws of grammar and rhetoric. But all these Dr. Garratt ignores.

In this volume there are jumbled together a great variety of descriptions of apparatus, of directions for employing them, and citations from learned authors on almost every department of human thought; but for any broad, compact generalizations in regard to the scientific employment of electricity, or for any intelligible rules in regard to the applications, we look in vain. His absurd and repeated violations of the simplest laws of composition, his turgid and meaningless amplifications, his *lucus a non lucendo* suggestions for practitioners, will surely cause all who are not endowed with more than usual self-control, to throw aside the volume in disgust, both with the subject and the author. We speak with deliberation when we say that the writings of Dr. Garratt have retarded more than they have advanced the cause of electro-therapeutics. Those who are already familiar with the details of electrical application may find in his larger work a verbose complication of what has thus far been attempted in this department, and may derive some assistance therefrom. But those inquiring minds who either in the original work or in the "Guide for using Medical Batteries," seek for information that may make them practical electricians, will be guided into darkness rather than into light. The subject of electro-therapeutics demands great energy, zeal, patience, and experience, on the part of him who would become proficient in it, but it is far from being as complicated and abstruse as Dr. Garratt would make us believe. We are firmly convinced that the medical use of electricity is destined to assume an importance of which its warmest advocates have at present no con-

ception; but it will be in spite of, and not by means of such works as these. In all friendliness and sincerity we urge upon Dr. Garratt to write no more; but if he must use his pen, let him condense this "condensation." Far better that there should be "silence for a century" on this subject than that there should by any multiplication of such works as "*Medical Electricity—Nervous Diseases*," or this "*Guide for using Medical Batteries.*"

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, January 9, 1867.

DR. FRANK H. HAMILTON, PRESIDENT, IN THE CHAIR.

DR. LOUIS BAUER presented the following specimens:

OSTITIS OF LOWER THIRD OF THIGH-BONE, AND PARTIAL DETACHMENT OF EPIPHYSIS SUCCEEDING AMPUTATION AT THE KNEE.

The patient is a lad of fourteen years, undersized, and of delicate organization, exhibiting no marks of puberty. On stepping from a ferry-boat, he missed his footing, got the lower part of his leg, the ankle-joint, and the tarsal portion of the foot jammed, lacerated, and comminuted. The attendant amputated at the knee-joint, after an inexplicable delay of five days, gangrene having supervened. The integuments appropriated for the covering of the stump sloughed away likewise, thus leaving the epiphysis fully exposed. Gradually, the stump became subject to a most intense pain, which had lasted eight weeks without cessation, when the patient came under my charge. His reduced and anæmic condition, the accelerated pulse and hectic symptoms generally, denoted continued and severe suffering. The lower portion of the stump was excessively tender to both touch and movement. The integuments surrounding the projecting bone were ragged, discolored, and œdematous; the discharge was copious, and of a sanious character; the epiphysis black, corroded, and soft, with but fragments of articular cartilage, loosely adherent. The epiphysis, moreover, was evidently loose, and might have been detached without much effort. The subcrurian bursa was slightly distended by fluid. Occasionally the stump would be shaken by spasms of the most painful character.

An early amputation of the diseased portion of the stump was deemed advisable, and the patient desired it most urgently. Whilst he was under the influence of chloroform, and being prepared for the operation, the stump was still so tender that a gentle touch produced lively reflex tremor. The amputation passed off without any remarkable incident, except that there was copious bleeding from the medullary cavity. The periosteum was but loosely adherent, and so much changed in texture that consecutive troubles of the bone were apprehended. Nevertheless, the wound closed rapidly by first intention, and the patient was about on the fourteenth day.

In viewing the specimen soon after its being removed and longitudinally divided, we found it exhibiting both hyperæmia, intensified by hæmorrhagic depositions, and hyperplasy towards the epiphysis; the reticular substance is notably densified, while the periosteum is internally covered with osseous elements—the creation of new bone. On the surface of the bone, similar rudimentary attempts are observable. The cartilaginous connexion between the shaft and its epiphysis was materially changed in thickness and consistence, being so soft as to almost allow a free antero-posterior movement. Its spontaneous separation was effected by a maceration of twenty-four hours.

The case may attract more surgical than pathological interest. The injury having been limited to the lower part of the extremity, left the thigh-bone intact. Its diseased condition accrued from the exposure of the epiphysis to the action of atmospheric air and purulent maceration, and thence it extended to the shaft. It would seem as if the amputation at the preferred point, under the preceding circumstances, was rather ill-conceived, inasmuch as the coverings of the stump had to be taken from parts in close proximity to tissues already mortified, and themselves, perhaps, more or less vitally depressed. Irrespective of this objection, however, a query arises, whether an amputation at the knee-joint, before puberty, is at all judicious? Dr. Markoe has the merit of having prominently urged that amputation on account of its statistical superiority. The cases adduced in its favor include, if I am correctly informed, two children; the closing of their stumps met with no protraction. With due respect for the accuracy and clinical skill of that gentleman, I entertain humble doubts as to the practicability of so general a rule. From my own experience, I am justified in inferring that there can be no direct union between the flaps and the articular cartilage; the latter has to undergo some prior structural changes which must inevitably protract the cicatrization. Whilst thus suppuration and the formation of granulation tissue is going on, the epiphysis is exposed to the corroding or macerating influence of pus, irrespective of the atmospheric air, and may eventually become necrotic. In its turn, secondary amputation would seem inevitable. This is merely speculative on my part, as indeed I have had but limited opportunities for watching the healing process of such wounds. But other surgeons must have had clinical experience to that effect; hence they have suggested the abscission of the articular face. Though I may not feel prepared to cope with the larger experience of Dr. Markoe, I may be justified in suggesting the revision of his arguments in favor of this operation.

FUNGOID DISEASE OF KNEE-JOINT. CARIES OF THE ARTICULATION. AMPUTATION.

The specimen, comprising the right knee-joint, may not be of great interest, as its pathological features are rather of ordinary occurrence. Nevertheless, it may serve to bring the term "fungoid disease," preferred by German surgeons, to a clearer comprehension among ourselves. The history of the case is of the usual character. The patient is twenty-seven years of age, slenderly built, delicately constituted, and a glass-blower by trade. Nevertheless, his health has been tolerably good, until he met with an accident to his articulation about three years ago. Ever since, the joint has given him trouble. But so insidiously did the disease advance, that during a part of the time he has been able to perform military service in the field, and in the Veteran Reserves, alias the "Diarrhœa Corps." Of late, however, the disease has made rapid progress, become so painful as to deprive him of rest and appetite, and consequently the patient has been much reduced in weight and appearance. About six weeks ago I took charge of the case. I found the joint but moderately flexed, at an angle of 120°, without much rotation of the leg, and eversion of the toes. The articulation had lost all its contours by distension and tumefaction. Above it, and in front, there was a large abscess, extending upwards over the lower third of the thigh. On the outer aspect there was a fistulous opening, leading to the

articular cavity. There was no other obstacle to the mobility of the joint than a moderate contraction of the biceps-muscle, and the excessive painfulness. On moving the joint, grating of bony surfaces could be discerned.

Although the case seemed to demand early amputation, nevertheless I resolved on freely opening the respective abscesses, on dividing the retracted biceps, and on placing the extremity in a proper, straight position, and to be guided by future exigencies. My reasons for this plan were to give the patient the chance, however remote, of preserving his extremity, and to give him instantaneous relief from pain, however temporary, so as to recruit his enfeebled condition, and thus prepare him for the eventuality of amputation. Moreover, the execution of the plan could be rendered, by chloroform, harmless, inasmuch as no material loss of blood was apprehended. My expectations were fully realized by the result following the procedure. The patient was indeed rendered comfortable, and enjoyed full immunity from pain for more than a fortnight. The discharge from the abscesses did, however, not improve in either quality or quantity, and after a fair trial I was impelled to resort to amputation, on the 30th ult. The patient sustained considerable loss of blood, in spite of the most rapid ligation. But two arteries required to be tied, whereas some thirty veins had to be secured; and besides that, the parenchyma oozed bloody serum freely. At one time during the operation, the patient became excessively debilitated; he rallied, however, by degrees, and is at present doing moderately well, the wound healing by suppuration. The periosteum was found to be greatly thickened, evidently caused by the extensive abscess along its course. This is probably the reason why the free incision into the joint had no lasting effect upon the condition of the patient.

The specimen presents but the ordinary characteristics. The articular surfaces are corroded, and but a few vestiges of cartilage remain loosely attached. The semilunar cartilages are changed in consistence and color, and partly destroyed by ulceration. The capsular ligament is perforated in three different places. The synovial membrane presents a condition described as "fungoid disease;" that is to say, it has undergone a transformation into cell-layers and granulation tissue, which project into the cavity, as folds and appendages, greatly infiltrated with serum. The peri-articular structure is much thickened, and pervaded with soft fat.

The terms "white-swelling," "tumor albus," and "fungus articuli," were formerly in use as synonyms. Of late, the appellation of "fungoid disease" has been adopted by German writers, not so much for the purpose of qualifying the general circumscribed intumescence of the joint and adjacent tissues, as to characterize the luxuriant growth and development of granulations that spring up from all sides, and overrun the articular surfaces like a multiferously ramified vine. This pathological condition is, however, not confined to the so-called chronic affections of the joints, but it may be observed, likewise, in wounds, fistulæ, and more particularly in the neighborhood of diseased bone; in fact, everywhere, where physical obstacles prevail against permanent cicatrization. This should be clearly understood, otherwise it might lead to the impression that the fungoid disease of joints comprises something pathologically specific, which of course does not exist. It is, in fine, the old disease with a new "trade-mark."

FALSE ANCHYLOSIS OF KNEE-JOINT. UNSUCCESSFUL ATTEMPTS AT FORCIBLE EXTENSION. SUBSEQUENT AMPUTATION.

The third specimen is of more than ordinary interest, inasmuch as it elucidates a variety of important pathological and clinical points. The patient is a girl, eight years of age A twist of the knee-joint two years ago, is alleged as the cause of the disease, which may have been aggravated by repeated falls. The general appearance of the patient implies constitutional derangement of nutrition, prevalent among all the other children of the family, although their parents are of indubitably good health. Fifteen months ago, at the request of her uncle, a respectable physician of Paterson, N. J., I took charge of the patient. She was then, as she is now, anæmic and attenuated, and had just passed through a very acute and painful attack of the disease, being still feverish, and without rest and appetite. The joint had lost its contours by peri-articular tumefaction. At its inner aspect there were two fistulous openings, leading into the articular cavity, and discharging but moderately serous fluid. The leg was angularly contracted, rotated, and the toes everted. There was still some mobility within a small angle. The biceps-muscle resisted further extension. Patella firmly adherent to the external condyle of the femur.

I suggested forcible extension of the limb, to be followed by subsequent absolute rest; and, eventually, the division of the biceps. This plan being accepted, I proceeded to its execution, the patient being under the full influence of chloroform. Bearing in mind the frail condition of the patient, and the loose connexion of epiphyses under such circumstances, I observed more than ordinary precautions to obviate accidents. After a few gentle movements of the joint in both directions, I became aware of a diastasis of the femoral epiphysis. This, of course, ended the procedure. The extremity was replaced in its previous position, and retained by proper means. No reaction followed, and the epiphysis eventually agglutinated firmly. The joint, itself, remained *in statu quo ante*. A fortnight ago I was urged to repeat the former trial, and I responded with still greater timidity. In order to remove the muscular resistance, I commenced the operation by dividing the tendon of the biceps-muscle not far from its insertion; and thereupon extended the limb by careful handling, gradually succeeding in bringing it to a straight position. As soon as I relinquished the traction of the leg, the joint bent again, as it were impelled by elastic tissue. I did not succeed in rupturing the inter-articular structure; I equally failed in returning the leg to its proper axis with the femur, or in detaching the patella. The result was, therefore, in the main unsatisfactory. On repeating the movements of the joint, it appeared as if the latter did not participate; and as if there was undue mobility between the shaft and epiphysis of the tibia. Whilst the extremity lay almost extended on the mattress, and I was preparing to adjust the retaining plaster-bandage, I made a last attempt to overcome the still existing resistance by a sudden, though gentle pressure, with the hand, upon the knee-joint; whereupon I noticed a crackling from above the joint, which I did not stop to investigate more closely. The accident induced me to replace the limb in its original position, which I thought soon to alter. Reaction of a very intense and painful character supervening, however, which the patient was not prepared to suffer, impelled amputation. I am happy to say that the patient is since doing well, promising a safe and speedy recovery.

The specimen is certainly of singular pathological interest. We notice, first, the angular position of the joint, in which it is held by soft and very elastic inter-articular tissue. In extending it, the tibia slides backwards on the femur; it subluxates, as it were. This movement of the tibia I misconstrued as bending upon its epiphysis. Had I left and secured the limb in the straight position,

a considerable pressure upon the popliteal nerves and vessels must have ensued, and prejudiced the recovery of the patient. It will be further observed that a rotation of the tibia on the femur is ineffectual, although the peri-articular structural complements are removed. The reasons are twofold. First, the tibia is turned by at least ninety degrees on its axis, so that its internal surface has become the anterior one, and its internal condyle protrudes considerably before that of the femur. In this position, the tibia is firmly retained by the inter-articular connexions. This is, indeed, the ordinary position in the like cases. Various theories have been proffered in explanation. Let us look at the clinical facts. Rotation and eversion supervene in affections of the knee-joint of some duration, and make their appearance *pari passu* with the contraction of the biceps-muscle. They accompany the angular malposition of the knee-joint. In this condition, most patients rest their limb on the outer surface, in which the biceps pulls diagonally. By this traction, not only flexion, but rotation of the leg also, is inevitably produced; as the members of the Society may notice when I imitate this action upon the remaining fragment of the tendon. It is more clearly seen in giving, first to the joint, an extended position, as far as it is susceptible, and then pulling at the tendon, you observe that the tibia follows in the direction of flexion and rotation. If this is correct, as it seems to ocular inspection, the *modus operandi* is clear, and the cause transparent. It explains, likewise, the reason why the patella rides on and agglutinates with the external condyle of the femur; because, through the rotation of the tibia, the anatomical relations are so changed, that the insertion of the ligamentum patellæ arrives below the external condyle of the femur; and the patella has, consequently, to yield, and to accommodate itself to the altered relation. In very aggravated cases, the patella may even slide over the external condyle of the femur, and thus give rise to knock-knee of the highest degree. On inspecting the joint, we notice that the articular cavity is almost entirely obliterated by inter-articular fibrous structure, leaving but a small space free. And so elastic is that fibrous tissue, that it prevents the contact of this portion of the joint, and, therefore, obviates the grating of the bony surfaces upon each other. In flexing the joint as much as possible, we have a glance at the condition of the corresponding two internal condyles. The tibia is simply corroded and softened; whereas, at the surface of the femoral condyle, a small sequestrum is noticeable, which is, however, not entirely detached. This space of the joint communicates, upwards, with the subcrurean bursa. I found the bursa lined with fibrinous material, partly organized, indicating that during the latter period of the disease inflammation has had access to that structure. Without destroying the instructiveness of the specimen, I cannot expose the cruciated ligaments. Below the internal condyle of the tibia, and alongside of the tuberosity of the tibia, the periosteum is destroyed in a circumference of a five cent piece, and to a larger extent detached from the bone. Most probably there is a free communication with the joint at the corresponding place, which I have not, however, been able to discover. In comparing the size of the respective epiphyses with each other, and that of the femur with its shaft, we observe considerable disparity. The shaft of the femur is so small in circumference, and its lower epiphysis so disproportionately large, that they could not be considered as belonging to the same bone, if disconnected. I possess a female skeleton, which represents, in its size and structure, the period of puberty; yet its femoral epiphyses are noticeably smaller than this specimen. The same disparity of size exists with the epiphysis of the tibia. The sequestrum, at the internal condyle of the femur, may have had something to do with this enlargement, but certainly not much, because the enlargement is general, and not confined to the affected spot; nor is there any evidence of an extensive disease of that portion of the joint. It would seem, therefore, that the previous diastasis had given rise to this hyperostosis; and, perhaps, the circumstance that the epiphysis is covered with cartilage to an extent not seen by me before, may corroborate the view which I feel disposed to take of this pathological fact.

The periosteum of the femur and its connective covering are materially thickened and readily detached. About two inches above the epiphysis the shaft of the femur is posteriorly infarcted to the extent of three-fourths of its diameter, which infarction was evidently caused on the occasion I have mentioned.

At the upper part of the popliteal space the periosteum is perforated by ulceration extending along a subperiosteal track of some two inches, without apparent connexion with the joint. The section of the femoral shaft seems to be disproportionately thin when compared with the diameter of the medullary cavity.

In viewing the specimen in its total aspect, it might be questioned whether the exsection of the knee-joint may not have been preferable to amputation, or whether the latter was at all justifiable. On these points I shall be glad to hear the opinions of surgical experts. I may, however, at the same time offer my own views on these questions. As a general thing, I am against all exsections of the knee-joint in children, and for two reasons. In the first place, if parts of the respective epiphyses are left, suppuration is very protracted, and in some instances the rest of the epiphyses being exposed to purulent maceration become detached, and are eventually thrown off as sequestra. Very few patients are in the condition to sustain the drain. But on removing the entire epiphyses at once, the limb becomes much shortened and its usefulness questionable. In the present instance I had no confidence in the restorative powers of the enfeebled patient, and had, therefore, no pretext for risking a profuse suppuration inevitably following exsection. In reference to the amputation referred, I had shown my disinclination to mutilate by the repeated unsuccessful attempts at saving the extremity. When violent reaction had set in after the second trial, nothing but the amputation could save the patient.

FIBROUS TUMOR OF UTERUS SURROUNDED BY ENCEPHALOID NODULES—COLLOID AND CYSTIC DISEASE OF OVARIES.

Six months ago I was called in consultation by Dr. Lord, of Brooklyn, upon an aged lady. In stepping down from a stage, she fell and fractured the neck of the right femur. We placed her upon a water-bed, employed extension by pulleys and weights, and rendered her condition comfortable and painless. A carcinomatous disease of the womb, previously acquired, led to her decease a few days ago. The post-mortem examination placed me in possession of this and another specimen.

The womb, it appeared, had been infested for some considerable time with a fibrous tumor in its anterior wall, of the size of a small orange, which, however, does not encroach upon the uterine cavity. Around the tumor there are several white nodules imbedded, which under the microscope have been recognised as encephaloid cancer from the fact of a very scanty stroma and multifariously shaped nucleolated cells. On the surface of the womb there are similar nodules, some of them pedunculated. The uterine cavity is empty, and extends over the whole length of the growth,

measuring not less than seven inches. The right ovary, the lesser of the two, has undergone the so-called colloid degeneration, and shows the honeycomb arrangement in a very instructive manner. The left one seems to be of similar structure, with additional cystic formation.

FRACTURE OF NECK OF FEMUR.

This specimen of the same patient presents all the peculiarities so well delineated by Dr. G. K. Smith, of Brooklyn, namely, the shortening of the neck of thigh-bone and the characteristic insertion of the capsular ligament. It is from these facts impossible to say whether the fracture was extra or intracystular, or both. There is, of course, no attempt at forming callus.

INTERNAL STRANGULATION OF SMALL INTESTINE THROUGH AN OPENING IN THE MESENTERY; DEATH WITHIN 27 HOURS.

The patient, a negro man of 37 years, alleged to have been well up to his late illness, was suddenly attacked with intense pain in the abdomen and incessant vomiting, proving uncontrollable by the efforts of his attendant. From the fact that a copious alvine discharge was effected, no apprehension seems to have been entertained of internal obstructions. The patient rapidly sank and died, at the 27th hour from the commencement of his trouble. Suspicions of poisoning having reached the coroner, I was summoned to make the post-mortem examination, when the cause of death was ascertained as "internal strangulation of small intestine." There is a perforation in the mesentery near the fastening of the gut in which two slings of the small intestine have become strangulated. Below the strangulation the latter was distended and discolored with extravasated venous blood partly located between the muscular and mucous coats, partly within the tube itself. There is no trace of inflammation. In the abdominal cavity there was but little bloody serum.

Dr. HAMILTON, in reference to Dr. Bauer's recommendation in the first case not to amputate at the knee-joint of children, on account of the liability to separation of the epiphysis, asked if the same objection would hold good in regard to other joints.

Dr. BAUER stated that he would raise the same objection.

Dr. SANDS did not think that experience would bear out this objection. He himself had performed two amputations at the knee-joint, in the New York Hospital, in children, aged respectively six and ten years. Both did well notwithstanding that in one of them the soft parts used for the flap had been injured, and had partly sloughed, while there was besides suppuration in the joint cavity and exfoliation of the articular lamellæ.

Dr. BAUER remarked that the recommendation to remove the cartilaginous surfaces of the joint in these cases had been made by other surgeons before him, and he was inclined to adopt their views upon the question for two reasons. I. That the cartilage is too apt to become detached and give rise to dangerous inflammation of the joint; and II., that the whole epiphyseal extremity might be detached as the result of the same morbid process and death ensue. After all, he considered the question an open one, as there had not been enough experience in this operation to warrant the forming of a positive opinion on the subject, as the whole number reported did not exceed fifty.

Dr. HAMILTON remarked that a statement concerning a matter of so much importance by a gentleman of such experience as Dr. Bauer, should not go unchallenged, more especially as the opinion of most other surgeons on this very question leaned in the opposite direction. The reason why these surgeons were of this opinion was, that they thought it less dangerous to leave a cartilaginous surface than to run the risk of inviting an attack of osteo-myelitis by invading the tissue of the bone itself.

Dr. BAUER expected to meet with this challenge. He did not pretend to offer any results of experience, but simply to state such convictions as his reasoning upon the subject had led him to adopt.

Dr. WOOD remarked that the first case of amputation of the knee-joint performed in this country was by an army surgeon, upon the person of a soldier who had been wounded in the Florida war. The case was afterwards brought to the New York Hospital, and so successful was the result that the operation became quite fashionable. He agreed with Dr. Hamilton that the dangers attending upon osteo-myelitis were prevented by leaving the cartilage; and stated that he had been in the habit of doing this and had never experienced any trouble. He remarked, as long as there was such danger from osteo-myelitis, that we should prefer the line of section through the knee-joint.

Dr. WOOD, in conclusion, stated that he had no experience in amputation at the knee-joint in children.

Dr. SANDS admitted that his two cases could by no means settle this question as far as children were concerned, but that they, nevertheless, were entitled to have their weight.

Dr. BAUER stated that amputation at the knee-joint upon children had been performed but a very few times, and Dr. Markoe, in his paper upon the subject, only reports two or three. The same could be said concerning other articles which had been written upon the operation.

Dr. SANDS exhibited two specimens of fracture of the neck of the femur occurring in the same individual.

In both instances Dr. S. remarked that the fracture was within the capsular ligament. The direction of the fracture upon the left side was from before backwards and from within outwards. The largest piece of bone attached to the head was posteriorly. Upon the other side the appearances of the fracture were somewhat similar to those of the specimen shown by Dr. Bauer. The line of fracture was from before backwards, and from within outwards. The union seems to have taken place by the ligamentous bands which pass from the articular surface of the head of the bone to the inter-trochanteric line, and by bands from the capsular ligament with the fracture surface; so that there was a very perfect false joint, and the head of the bone moved partly upon the capsular ligament and partly upon the inter-trochanteric line.

The right limb was thirty-two inches in length and the left twenty-nine and a half. The cause of death was the effusion of blood upon the surface of the brain.

Dr. WOOD stated that the case to which the specimens belonged was treated by extension the same as in fracture of the thigh, and a fair chance was given for bony union in case there was any disposition for the fractured ends so to do. He further remarked that in both instances of the fracture the patient fell upon the respective trochanter. His opinion was, that in the case of the left femur the fracture was partly within and partly without the capsule.

Dr. HAMILTON called attention to the manner in which the injury was inflicted in reference to the experiments of Rodet. That gentleman states that when the blow was directly upon the trochanter from without, the fracture was extra-capsular; if from behind or below, intra-capsular; if from behind and without, partly within and partly without, the capsule. He be-

lieved that in the main the observations were correct, but the conclusions based upon them were altogether too exclusive. He had seen many cases in old persons where the blow upon the trochanter from without had resulted in intra-capsular lesion.

Dr. Bauer asked Dr. H. what were the statistics of the treatment of those cases partly within and partly without.

Dr. Hamilton answered by saying that he was not possessed of any means to determine when this condition of lesion existed. He did not think that there was any evidence that fractures within the capsule ever united by bone.

Dr. Bauer coincided in this opinion and had been in the habit of acting accordingly, by allowing the patient to walk about by the aid of his splint within eight or nine days after the accident or as soon as the swelling had subsided.

Dr. Hamilton remarked that the only argument in favor of treatment was the difficulty of making a diagnosis as to whether the fracture was wholly without the capsule or not.

Dr. Wood corroborated this statement, but was inclined to give his patients, especially those not far advanced in years, the benefit of a doubt, by placing them for a certain time upon a double inclined plane.

Dr. Messinger referred to a case of fracture of the neck of the thigh bone occurring in a lady ninety-four years of age, whom he treated in conjunction with Dr. Buck. The patient recovered sufficiently to get about comfortably until she was a hundred years old. She was treated upon a double inclined plane, although it was not claimed that bony union had taken place.

The Society then adjourned.

EAST RIVER MEDICAL ASSOCIATION.

Stated Meeting, March 5, 1867.

Dr. V. Morse, President, in the Chair.

THE EFFECTS OF ALCOHOLIC LIQUOR ON THE FATALITY OF CHOLERA.

Dr. Thoms read a statistical paper upon the above subject, which was thoroughly and ably discussed. In support of his view he remarked, that the diagram accompanying his paper on the *Effects of Alcoholic Liquors upon the Public Health*, indicated the fact that the death-rate from cholera was greatest in those wards where the hospitals were established during the prevalence of the epidemic. The summary of our statistical knowledge may be given in the following figures:

The First, Fourth, Sixth, Twelfth, Fourteenth, and Twenty-second Wards have shown a death-rate from this disease of under one in every thousand of the population, while the Eleventh, Fifteenth, Eighteenth, and Twenty-first foot up a death-rate of over 1 in 5,000.

The wards where the predisposing elements of cholera are most unmistakably found are the First, where the deaths from cholera were 1 in 489, against 1 in 22 from all other causes; in the Fourth, where the ratio was from cholera, 1 in 576 to 1 in 26 from other influences; and in the Sixth, cholera claimed 1 victim out of every 212 of its population, while 1 out of 24 perished from diseases, casualties, etc.

The Twelfth, Fourteenth, and Twenty-second Wards, where the malarial influence predisposing to an attack of the disease was most rife, presented us with the following mortuary record: The Twelfth, a death-rate from cholera of 1 in 760, from all causes 1 in 52; the Fourteenth, from cholera 1 in 756, from all causes 1 in 30; the Twenty-Second, from cholera 1 in 908, from all causes 1 in 43.

Cholera hospitals, during the epidemic, were established in the First, Twelfth, and Twenty-second Wards, which, owing to the contagious character of the disease, may have augmented the death-rate.

THE INUNCTION OF BELLADONNA IN STRANGULATED HERNIA.

Dr. Weisse reported the following case: He had been called to a young man, who, upon the day previous, felt something give way in the groin, while lifting a barrel of "*lager bier*." A tumor appeared, which increased in both size and hardness, so much so, that some hours after the accident, when he first saw him, the implicated parts were as hard as marble. He diagnosticated a strangulated hernia, and resorted to taxis without success. After having become thoroughly convinced that surgical interference was necessary, he left the case for the purpose of procuring the necessary aid, merely directing, during his absence, the inunction of the *Ung. Belladonnæ* (℥ i *ad* ℥ i) with the proper amount of gentle but continued force. He returned in an hour with Dr. Stein and prepared to operate, but was agreeably surprised to find that the tumor had, meanwhile, become soft and capable of being kneaded like dough. Taxis again failed, when the idea of throwing the patient into the position best adapted for bringing the weight of the intestines into play, occurred to him. This he did not claim as original, since it had been discussed in some of the British journals, but he desired to go a step further and avail himself of their *recoil* after impingement against the abdominal walls. In carrying out this method of treatment, he was ably seconded by his colleague, who made the necessary lunges with the patient's body at the given signal. The third attempt was successful; the usual gurgling sound of a returning intestine relieving them of their present anxieties.

He had got the hint of treatment by belladonna from a French medical journal, in which it was related that a physician, after exhausting all the recommended expedients, had concluded upon division of the stricture as the last resort. But, to this, the patient, having a horror of the knife, most strenuously objected. Belladonna, with the view to relieve the pain only, then suggested itself, when the parts soon became so relaxed that taxis accomplished the desired reduction. He repeated the report to the late Prof. V. Mott, who was quite favorably impressed with its feasibility, and desired him to put it to the test upon the first opportunity, which, as related, had just presented itself.

The points of interest in the case, he thought, were (1.) The effect of the belladonna; and (2.) The advantages gained by the recoil of the intestine.

Without wishing to extravagantly praise belladonna, he certainly thought that it had not yet attained its proper rank in the materia medica. It might be employed, in his opinion, in nearly all those cases where the poison of the disease manifested itself through the medium of a contracted or insensible pupil, which, in turn, showed some profound impression upon the sympathetic nervous system.

Dr. T. Nichols had fallen into the habit, especially in the case of children, of examining the state of the pupil, and from it had derived some very valuable therapeutical hints. He frequently used belladonna in scarlatina, and was disposed to look upon it as a valuable agent destined to replace opium, which seemed, in the minds of some practitioners, to exclude the suggestion of every other anodyne.

To be continued.

Correspondence.

MEDICAL MATTERS IN CHICAGO.

To the Editor of the Medical Record.

Sir—Our medical colleges have at length completed their winter terms, and have graduated a large number of students. The concluding exercises at the Rush Medical College were of a character less brilliant than would have been the case, had the much-lamented Brainard lived to honor the occasion by his presence. It was, nevertheless, a goodly class of young men—seventy-two in number—who were mustered to receive their diplomas from the hands of their President, Professor Blaney, who is now the sole survivor of those famous pioneers by whom the college was founded. These anniversary exercises received additional interest from the fact that they occurred for the last time in the old college hall. The return of spring will introduce a new era in the history of "Old Rush." A new building will be commenced upon a site adjacent to the one now occupied. In this, when completed, will be the lecture-rooms, and the apartments of the faculty, while the old structure will be renovated and adapted for the reception of the museum and the school of practical anatomy. To occupy the vacant chair of surgery comes Professor Moses Gunn, late of Detroit. Abandoning his professorship in the University of Michigan, he now transfers his residence to this city. Already well known as a lecturer, his great reputation cannot fail to be of service to an institution which has owed so large a portion of its success to the fame of its teachings in the matter of surgery.

The graduating exercises of the Chicago Medical College occurred yesterday afternoon. The degree of M.D. was conferred upon thirty-three young men—the largest class that has ever graduated from that institution. The number of students in attendance upon lectures during the past winter has been one hundred and eight. The increasing popularity of this excellent school is one of the most encouraging signs of the times, and furnishes a sufficient refutation of the arguments urged against the measures which are now being discussed in behalf of an elevation of the standard of medical education. In this school the students are classified as juniors and seniors. The course of lectures is also divided in like manner, so that while one class listens to the professors, the other is engaged in the dissecting-room. At the close of the winter term the juniors are required to pass a searching examination before they can be advanced to the senior class. The method of review by daily recitation is also enforced in both classes. The length of the winter term is five months, and to this is added a spring term of three months. Thus we have here provided a system of medical instruction which is not excelled by any other school in the country; and it appears self-evident that if this method of instruction has been so far successful, in spite of the rivalry of all the other schools, it cannot fail to give universal satisfaction, when the concerted action of our college faculties shall require as much from every candidate for a medical degree. It is impossible to refain from expressing the hope that the proposed conference of delegates, meeting in Cincinnati next summer, may result in the abandonment of a policy for which only the poverty of our ancestors could be an excuse. Our modern sense of propriety should instantly decree the suppression of such an old-time exhibition as still finds favor with too many of our medical school faculties.

The medical students who have passed the winter in our city have enjoyed such opportunities for clinical study as have never before been furnished in the North-west. Our county hospital, located in this city, has now been open for one year. In all the details of its management, it is a miniature edition of Bellevue Hospital. Twice a week during the winter, it has been opened to the students; and they have literally *thronged* the building. Never, even in Bellevue, have I witnessed such eager pursuit of the clinical lecturers; such desperate struggling for standing-room in the dead-house. Though obliged to come a distance of three miles from the college, the students would crowd the amphitheatre of the hospital, every Tuesday and Friday, to a degree only matched in New York by the attendance upon one of Dr. Wood's especial field-days. Our western students are a working class of young men, and none of them are willing to lose a single one of the opportunities afforded during their brief term of metropolitan study.

The Chicago *Medical Journal* has once more changed hands, returning again to the care of a former editor, J. Adams Allen, M.D., Professor of Theory and Practice in Rush Medical College. The Journal will continue to be, as heretofore, the organ of the college; and at the present time may become a very convenient means of advertising the alumni of the changes through which their *alma mater* is passing.

Our State Legislature has recently passed a bill for the establishment of a Health Commission for this city. The special provisions of the act have not yet been given to the public, but rumor reports a general conformity with the features of the New York enactment.

The past winter has been a season of remarkable health. Great uniformity of temperature, combined with an unusual precipitation of snow, has reduced the death-rate to a very low figure. The variable weather of spring will soon increase the tendency to disease, and then our long winter vacation will be over. During the month of February the number of deaths reported to the health officer, including all the cases of still-birth, were only two hundred and fifty-five, in a population of two hundred thousand. Excluding still-births, the mortality in January was two hundred and seventy-seven. During the year 1866, notwithstanding the prevalence of cholera, which destroyed nine hundred and eighty-seven lives, the total mortality was only 5,926, being equivalent to a death-rate of a trifle less than 30 to the 1,000 living, or, excluding the victims of cholera, a trifle over 24 to the 1,000 of population. This favorable exhibit is by no means due to the superiority of our climate, or to an advanced state of sanitary intelligence, but to the absence of tenement houses, and to the youth of the mass of the community. When the extreme of hoary age shall begin to add its quota to our returns of mortality, the annual death-rates will undoubtedly exceed their present figure. M.

COMMENCEMENTS OF THE COLLEGES OF PHILADELPHIA.

FEMALE PHYSICIANS, ETC.

Philadelphia, March 16, 1867.

To the Editor of the Medical Record.

Sir—The past week has been full of interest to the medical profession of this city. Our medical colleges have sent forth their quota of graduates, and our County Medical Society has had an animated discussion as to the status of medical practitioners of the gentler sex.

At the public commencement of the Jefferson Medical College, held on the 9th of March, the degree of

Doctor of Medicine was conferred by the Hon. Edward King, LL.D., President of the Institution, upon one hundred and fifty graduates, after which the valedictory address was delivered by Prof. BIDDLE, of the chair of Materia Medica. Dr. Biddle's address was admirably adapted to the occasion, and abounded in valuable counsel, not least of which was the advice to avoid two great impediments to success in practice, one being the maelstrom of politics, and the other the fascinating pursuit of special departments of science; for the field of medicine is itself amply sufficient to employ the entire talents of the physician. He also recommended a strict adherence to the Code of Ethics of the American Medical Association, and active membership in a medical society.

On the 14th of March the annual commencement of the Medical Department of the University of Pennsylvania was held at the Philadelphia Academy of Music, and the degree of M.D. was conferred upon 156 graduates. An excellent and affectionate valedictory address was given by Prof. CARSON, who also counselled strict adherence to the national code of ethics, and connexion with local medical organizations.

The number of graduates from Pennsylvania was in large proportion in both institutions, being 70 at the Jefferson Medical College, and 99 at the University. The number of matriculants during the course was 356 at the Jefferson, 168 of whom were Pennsylvanians; and 464 at the Medical Department of the University, of whom 307 belonged to Pennsylvania, leaving 188 from other States at the Jefferson, and 157 outside of our own State at the University.

On the evening of the 13th there was assembled at the conversational meeting of the Philadelphia County Medical Society, a larger number of members than usually attend; the subject for discussion being the report of the committee on Female Physicians.

At the meeting of the Medical Society of the State of Pennsylvania, held in 1866, there was passed a resolution to the effect that it was considered unprofessional to consult with the professors and graduates of female medical colleges, as at that time organized. At the meeting held last year at Wilkesbarre, a resolution was introduced to repeal the former resolution, which was lost by a very closely contested vote; and another resolution was offered to the effect that nothing in the resolution of 1860 should be so construed as to prevent members who so desired, from consulting with properly qualified female practitioners; and for this was substituted and passed another postponing further consideration for a year, and recommending the discussion of the subject in the interim by the various county medical societies. On this subject see my letter in No. 9, p. 220, vol. I., of THE RECORD.

On the evening in question the report of the Committee, as prepared by the chairman, Dr. D. Francis Condie, was read by that gentleman. This admirable report, covering the entire ground, I hope to give you in full, in a regular report of the proceedings of the Society. The report acknowledged the capability of the female mind to accomplish anything intellectually that can be acquired by the male; at the same time it was strenuously opposed to encouraging females to devote themselves to this sphere of usefulness, unless only so far as to properly fit them for intelligent nursing of sick, with which the proper mission of woman, in this direction, was attained; but, inasmuch as certain women *would* undertake the study and practice of medicine, and their services would be solicited by a large number of invalids, our duty to the community at large demanded that the profession should see that such females could have access to proper instruction, and that if such were the case, it would be improper to refuse to consult with them. The report suggested their attendance at the same medical institutions as the male student, and under the same discipline; and that if it should be deemed inexpedient to permit their presence in the lecture-room at the same time with male students, the same lectures should be delivered to females at different hours. The report concluded with a resolution adverse to the repeal of the resolution of 1860.

An animated discussion ensued, which was participated in by many of the members, and a resolution to the effect that the matter should be referred to the American Medical Association, was laid over for action at a special meeting, at which it is hoped a larger attendance will secure an action fully representing the views of the profession.

The lectures of the Auxiliary Faculty of Medicine of the University of Pennsylvania, embracing various branches of natural history with special reference to their medical relations, will commence in April, and be on the same subjects and by the same professors as last year. The Summer Course of Lectures inaugurated last year at the Jefferson Medical College, will be resumed the coming summer, but the scheme has undergone some modification in subjects and lecturers.

This course will be as follows:—

Clinical Surgery, by Prof. Gross.
Clinic of Diseases of Women and Children, by Prof. Wallace.
Chemistry applied to Toxicology, by Prof. Rand.
Materia Medica and Therapeutics, by Prof. Biddle.
Clinical Medicine, by Dr. Da Costa.
Visceral and Surgical Anatomy, by Dr. W. H. Pancoast.
Operative and Minor Surgery, by Dr. J. H. Brinton.
Ophthalmic and Aural Surgery, by Dr. R. J. Levis.
Venereal Diseases, by Dr. F. F. Maury.
Pathological Anatomy, by Dr. W. W. Keen, Jr.

It is gratifying to be able to chronicle here one new and valuable movement in a proper direction, and that is the teaching of Pathological Anatomy. The sooner that this branch is made part of the regular winter curriculum of studies, the better. I believe that the Harvard School is the only one at which it has heretofore been regularly introduced, and the necessity exists for following this example wherever medicine is taught. At present but little knowledge of pathological anatomy is conveyed to the student, and that little is taught incidentally with other branches. The establishment of a separate chair of Pathological Anatomy would relieve the chairs of Practice and of Surgery to a great extent, so that the professors of these practical branches would have time to teach them more thoroughly. As it is, in more than one instance but partial courses are given in these practical subjects, and the study of many important diseases is entirely neglected. This fact should be borne prominently in mind when the representatives of the various medical faculties meet in convention at Cincinnati in May next.

In this connexion you will be glad to learn that DR. ALFRED STILLÉ, Professor of the Practice of Medicine in the University of Pennsylvania, made MORBID ANATOMY the subject of a lecture, introductory to the course of clinical instruction at the Philadelphia Hospital for the winter session of 1866-7; and he has been sufficiently impressed with its importance to have his lecture printed in pamphlet form, a copy of which should be placed in the possession of every one interested in progressive medical education. One or two extracts from this timely and admirable lecture will be in place.

"I shall endeavor to show you that morbid anatomy

is an indispensable element of medical science, that its position is a fundamental one, and that it is indeed the very corner-stone of that science. Let me attract your attention towards it and fix your interest upon it; let me move you to share the wonder which I feel, and which I can scarcely find words to express, that in neither of the great schools of this city does there exist a professorship devoted exclusively to a scientific exposition of pathological anatomy.

"A description of disease without an accurate account of the lesions which accompany it, is like a drama, or a tale, or a history, which stops short before the catastrophe that explains and justifies, and gives an interest to all that has gone before. Morbid anatomy draws the veil aside which conceals the machinery upon whose movements all the phenomena of disease depend, and it, alone, relieves us from the superstition which once pervaded the medical world, that every disease is a diabolical inhabitant of the body which is to be exorcised by charms and incantations.

"Without the revelations of morbid anatomy we should possess as little knowledge of the nature and seat of diseases, as the physician of an oriental harem, who is obliged to prescribe for his fair patients without being allowed either to see or to touch them. Symptoms are the inarticulate cries for relief of suffering organs. Woe to the sick if we have not learned to interpret their language! The keys to its meaning are not only interrogation, but also inspection and all the methods of physical examination, which, after all, are so many lessons in morbid anatomy; for they enable us to discover the seats of disease and the changes of structure which it involves."

And the lecture concludes: "If you shall become duly impressed with the extreme interest and the incalculable value of morbid anatomy to yourselves and to all disciples of the healing art, unite your voices in an appeal to those who regulate the studies of our Medical Institutions, and solicit them to put an end to the great defect of medical education which we now have to deplore. Importune them to create in every Medical College a chair from which the science of morbid anatomy shall be adequately taught, so that you and your successors may cease to lament the imperfect and unscientific notions of disease which you are now too often compelled to accept, and which, so long as they continue to prevail, will oblige American Medical Science to walk with uncertain steps and veiled countenance behind her European sister."

The above quotations need no commendatory comment; they have been introduced here in the hope that the views of one of our most eminent teachers of medicine will be brought, through the medium of your extensive circulation, to the knowledge of many preceptors whom the pamphlet will not reach, in order that they, too, may unite their voices in an appeal for the removal of a great defect in medical instruction.

Yours truly,

C. J.

OVARIOTOMY PERFORMED TWICE SUCCESSFULLY UPON THE SAME PATIENT BY THE SAME SURGEON.

To the Editor of the Medical Record.

Sir—Dr. Spencer Wells, before the *Royal Medical and Chirurgical Society* (*London Lancet*, Feb. 1867), alludes to three cases in which ovariotomy has been twice performed upon the same patient. The author refers to a fourth case, "believed" by him to be the first, in which ovariotomy has been successfully twice performed upon the same patient by the same surgeon. In this case Dr. Wells removed the left ovary in February, 1865. In about eighteen months and one half after the first operation, the right ovary was also "removed with complete success."

I submit the report of a case upon which I have *successfully* operated twice. The patient was Mrs. Ellen Simmons, of South Bristol, Ontario county, N. Y. I removed the left ovary April 14, 1858. The case is reported in detail in the *American Journal of Medical Sciences*, October, 1858. The tumor weighed thirty pounds: the patient recovered; the right ovary was then healthy.

During the month of July, 1859, the patient discovered the second tumor, which increased so rapidly that on the eleventh of September, 1859, I was called to visit her.

On the twelfth I drew from the tumor about twenty pounds of fluid, and on the thirteenth she menstruated.

I decided to operate, which I did on the twenty-first of September, 1859—seventeen months and six days from the first operation. Chloroform having been given, an incision was made through the old cicatrix. The tumor, weighing thirty pounds, was removed; the pedicle secured by a single ligature; the wound united by sutures, dressed with a compress and corset-bandage, and the patient made a second recovery.

I was assisted in this operation by Drs. Jewitt and Carson, of Canandaigua; Durgan, of South Bristol; Parmely, of West Bloomfield, and Peltier, of Buffalo. *My operations were, therefore, performed nearly six years before those by Dr. Wells, and, accordingly, my case is believed to be the first in which ovariotomy was ever successfully performed twice upon the same patient by the same surgeon.*

Desiring to honor American Surgery rather than myself in this interesting matter,

I am, sir,

Your obedient servant,

Hazard A. Potter, M.D.

Geneva, N. Y., March 17, 1867.

THE INSTITUTION FOR RUPTURED AND CRIPPLED.

A CASE PRESENTED TO THE PATHOLOGICAL SOCIETY.

To the Editor of the Medical Record.

Sir—I have just read your published report in the first of March number, of the transactions of the Pathological Society of Nov. 28, 1866, and regret to see myself represented as stating what I never had any grounds for doing, viz. that "next he entered the Institution for the ruptured and crippled, where he remained under treatment for the greater part of two years," alluding to the boy whose hip-joint disease had fallen to my care, and whose history was related on that occasion. It was never my understanding of his history that this boy had been treated at the institution named, as a resident patient, and I therefore never intended to say so. Please, therefore, to allow, in the interest of those who may be concerned, and of truth, a correction of that report. I intended to state, what I then knew, and still believe, *that this patient was under the care and treatment of said institution for about two years before I saw him.* It was, however, as an out-patient, according to all the information I ever could get upon the matter. Please, give this an early place, and oblige those whom the report may affect unfavorably, as well as

Yours very truly,

Stephen Rogers.

March 2, 1867.

ON THE ACTION OF MEDICINE ON THE SYSTEM. By FREDERICK WILLIAM HEADLAND, M.D., B.A., F.L.S., Fellow of the Royal College of Physicians. 5th American, from 4th London Edition, Revised and Enlarged. Phil.: LINDSAY & BLAKISTON. 1867.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF NORTH CAROLINA. 1867.

Medical News and Items.

CLITORIDECTOMY.—Mr. Baker Brown and Mr. Philip Harper, in deference to the opinion of the medical press on the subject of clitoridectomy, have determined not to perform the operation in the London Surgical Home, pending professional inquiry into its validity as a scientific and justifiable operation. What now will be the chance of recovery for the poor epileptic female with a clitoris?

SMALL-POX IN LONDON.—Small-pox is prevailing to a frightful extent in London. Altogether there have been four hundred and sixty-two lives lost by this one disease in the space of thirteen weeks—an aggregate which may without exaggeration be spoken of as really alarming. It is most sad to reflect on the ignorant carelessness or the reckless folly of those who not only endanger the lives of their children and of themselves, but also jeopardize the lives of their neighbors and of the public generally, by neglect of the simple means available for reducing the baneful power of small-pox to a nullity. It is important that it should be known, moreover, that throughout the country—in large towns and rural districts alike—this loathsome and deadly malady is spreading, as well as in London.—*Lancet.*

WARNING AGAINST THE SIMULTANEOUS PRESCRIPTION OF CHLORATE OF POTASS AND IODIDE OF POTASSIUM.—This has great importance; since in syphilitic and other affections these drugs are often combined. But M. Vee has demonstrated the danger of such practice by showing that the chlorate of potass gives up its oxygen, which forms with the iodide of potassium an *iodate*, whose toxic properties have been recently demonstrated by Melsen.—*Gazette Médicale.*

FERRUM REDACTUM.—Metallic iron with a variable amount of magnetic oxide of iron, prepared by reducing peroxide of iron to the metallic state, by heating it in a gun-barrel in a furnace and passing through it dry hydrogen gas. A powerful hæmatinic and tonic. . . . . Dose, gr. ij.—gr. vj.—*Waring's Practical Therapeutics.*

TO DETECT SULPHURIC ACID IN VINEGAR.—A German journal publishes a neat process, which may be thus briefly stated. Into the vinegar to be tested, put a small quantity of starch, boil the solution down to half its original measure, then drop into it a very minute portion of iodine. If the vinegar is pure the usual blue tint will be shown, but if it be adulterated with sulphuric acid no such coloration will take place, because the action of this acid upon starch converts it into glucose or grape sugar.

OSMOTIC PROCESS FOR SEPARATING SUGAR.—In France sugar has been lately separated from beet molasses by applying the osmose principle. The membrane used is paper-parchment. Water is passed upwards and molasses downwards on the opposite side of the membrane.

ANECDOTE OF THE LATE PROF. DAVID S. CONANT.—An instance illustrative of his coolness and boldness may be briefly adverted to. On one of his visits to his home he found his father suffering from a cervical tumor. The disease had already developed to such an extent as to threaten suffocation by pressure on the trachea, and was manifestly malignant. Satisfied that the danger of sudden death was imminent, he determined to remove as much of the mass as practicable to relieve the pressure. In the course of the operation, he came upon the carotid artery. Without any hesitation he applied a ligature, and then extirpated all of the mass that could be safely removed. This operation gave great relief, and undoubtedly prolonged the father's life some months. It is not every surgeon, however, who could use the knife on his own parent, for at best only a palliative operation. —*Memorial Address, Prof. A. B. Crosby, Univ. Vermont Medical Department.*

CHARITABLE BEQUESTS.—Paschal P. Pope, of Boston, recently deceased, bequeathed $190,000, as follows:—To Harvard College, $50,000, for a Professorship of Latin Language and Literature; Home for Aged Men, $30,000: Sailors' Snug Harbor, $30,000; Boston Dispensary, $20,000; Harvard Benevolent Society, $20,000; Boston Society of Natural History, $20,000; the Temporary Home for the Destitute, $10,000; Boston Provident Association, $10,000.

THE THERAPEUTICS OF INHALATION.—TO THE PROFESSION.—Dr. J. Solis Cohen, of Philadelphia, is engaged in preparing for publication a work upon "*The Value of Inhalations in the Treatment of Disease*," and he requests the assistance of his professional brethren in supplying clinical material. Contributions will be duly acknowledged, and attention drawn to every source from which instruction may be derived. Negative results, and results apparently or actually unfavorable, will be of peculiar value. Even isolated observations will be of service. Information is more particularly desired as to results from inhalations in sore throat in all its varieties, croup, diphtheria, œdema of the glottis, asthma, and phthisis. Where other treatment has been conjoined with inhalation, mention should be made of at least its general character, and an estimate be formed of its value. Where favorable results are reported, an opinion is requested as to the probability of equally favorable results, had inhalation not been resorted to. Any general information on the subject in the possession of the writer will be placed at the disposal of correspondents intending to contribute their own observations. For the past few years this subject has attracted a great deal of attention abroad and at home, and a series of statistics of its therapeutic results, collated from the experience of American physicians in different sections of our country, cannot fail to prove of great professional value. We invite our readers to coöperate with him. Address, Dr. J. Solis Cohen, 1106 Walnut street, Philadelphia.

DEATH OF DR. WILLIAM JOHNSON OF WHITE HOUSE, N. J. —At White House, Hunterdon co., N. J., January 13, 1867, Dr. William Johnson died in the 78th year of his age. He was born at Princeton, N. J., on the 18th of February, 1789. His father, Thomas P. Johnson, was a lawyer of distinguished ability, and was one among few in this State upon whom was conferred the honorary degree of Sergeant-at-Law. His mother was a member of the distinguished Stockton family, many of whom have held important offices in State and National trust. At the early age of twelve years death deprived him of the sympathy and guidance of his mother, and he was left to the guidance, the wisdom of his distinguished father. After his graduation from the University of Pennsylvania he

settled at White House, N. J., in July, 1811. He soon fell into a wide and laborious practice, to which he devoted himself with singular fidelity and zeal. With a vigorous and active mind, he was a most laborious student, and constantly brought to his practice the results of patient research and study; added to this, he wrote with much clearness, elegance, and force. He furnished articles for different medical periodicals until blindness compelled him to abandon both his pen and practice. As might be expected, he was a skilful practitioner, and enjoyed a wide reputation. Many also sought his presence that they might sit at his feet as pupils of Galen.

CHANGES IN THE FACULTY OF PARIS.—The vacant chairs in the Faculty of Medicine of Paris have been filled as follows:—Professor of General Pathology and Therapeutics, Lassaigne; Professor of Pathological Anatomy, Vulpian; Professor of Therapeutics and Materia Medica, See; Professor of External Pathology, Broca; Professor of Internal Pathology, Oxenfeld; Professor of Internal Pathology, Hardy; Adjunct-Professor to the same chair, Raynaud. The resignation of Nelaton is spoken of.

A HOSPITAL FOR NERVOUS DISEASES.—An institution for the treatment of paralysis, epilepsy, and other nervous diseases, will be opened at Lake Mahopac, Putnam co., N. Y., in the early part of this spring. It will be strictly private, and under the direction of Dr. M. Gonzalez Echeverria, who is so favorably known in connexion with the practice of the specialty. In addition to the best comfort and to the natural advantages of the location, every means of special treatment beneficial for this class of diseases will be afforded to the patients. The institution will be provided with a room for light gymnastics, the proper apparatus for the exercise of paralytics, and the conveniences to administer the different kinds of baths.

ANNUAL COMMENCEMENT OF THE COLLEGE OF PHYSICIANS AND SURGEONS.—The seventieth annual commencement of the College of Physicians and Surgeons took place at Steinway Hall March 14th, a large and fashionable audience honoring the occasion with their presence The President of the College, Edward Delafield, M. D., the members of the faculty, the Trustees of the College of Physicians and Surgeons and of Columbia College, as also several prominent physicians of this and the neighboring cities, occupied seats on the platform. The proceedings were opened with prayer by the Right Rev. H. A. Neely, D. D., Episcopal Bishop of Maine. The Degree of Doctor of Medicine was then conferred on ninety-nine young gentlemen.

Upon the conclusion of this ceremony, Professors Clark and Dalton announced the prizes as follows:—first Harsen prize to J. Ackerman Coles, A. B., of New Jersey; second to D. Valentine Lynch, of New York city. The two faculty prizes were awarded, first to Albert H. Buck, A. B., of New York city for a thesis on "*Trichina Spiralis*," and the second to Ira Remsen, of New York city, for a thesis on "The Fatty Degeneration of the Liver." In connection with these latter prizes, honorable mention was made of the theses presented by the following graduates: Jonathan Edwards, Jr., of Rensselaer county, N. Y., Henry E. Handerson, A. M. of New York city; Roger S. Tracy, A. B., of New York city.

The address to the graduates was then pronounced by the Rev. Henry W. Bellows, D. D. It was a well-conceived tribute to the medical profession, and was well received by the audience. The valedictory address was delivered by William H. Palmer, A. B., M. D., after which the exercises were closed with the benediction.

ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS N. Y.—The ninth annual meeting was held at the College building corner Twenty-third Street and Fourth Avenue on Friday March 15th ult. The President, Prof. Alfred C. Post delivered the inaugural address in which he reviewed in epitome the progress made in the healing and kindred Arts for the past 60 years.

The Committee on award of the "*Delafield* Prize," reported that but one essay had been offered in competition which, notwithstanding the industry and care manifested in the preparation, was, under the circumstances, scarcely entitled to the prize, The Committee recommended that the fund be increased to $3,000, the interest of which should be devoted to the furtherance of the object intended. The designation of the Prize, at the urgent request of Dr. Delafield, was changed to that of the "*Alumni Association*;" and a subsequent motion that the fund be increased to the desired amount by voluntary subscriptions among the graduates prevailed. A Committee was then appointed to make the necessary appeals. After an animated debate, in which Drs. Parker, Eliot, Draper, Watts and Calkins participated, the subject of the Essay was left as during the past year "to the option of the Competitor" and under the same restrictions. Much interest was manifested in the "necrological record" which was read by the Secretary, Dr. Eliot. This custom, according to the *Historiological and Genealogical Register* for 1860, from which the Secretary quoted, appears to have been originated by the late Prof. J. L. Kingsley at Yale College in 1842, and was afterwards adopted at "Harvard" in 1851, at the suggestion of the late Hon. Edward Everett; Joseph Palmer, M.D., being the necrologist in the latter seat of learning for that and several succeeding years. The report was received with thanks, and the Secretary instructed to prepare from materials in hand a record of all deceased alumni for future reference. The following officers were elected for the ensuing year: *President*, Dr. Gurdon; *Vice President*, Dr. Galen Carter; *Recording Secretary*, Dr. Ellsworth Eliot; *Corresponding Secretary*, Dr. John Shrady; *Treasurer*, Dr. Henry B. Sands.

The Committee on Prize Essays consisting of Drs. William H. Draper and William E. Roberts was combined. The Councillors re-elected, the only change being the substitution of the name of Ezra M. Hunt of New Jersey, for that of Surgeon Charles S. Tripler, U. S. A., deceased. The numerous assemblage then adjourned to the Ashland House, where a liberal collation prepared by the faculty of the College awaited them.

THE SPRINGFIELD SOCIETY FOR MEDICAL IMPROVEMENT, is the name of the society which has recently been organized in Illinois, in accordance with the general statutes made and provided, and which, in the main, patterns after a similar society in Boston. Its organization, objects, etc., are in brief as follows:—Secretary and Treasurer, G. S. Stebbins, M.D.; Cabinet-keeper and Librarian, W. W. Gardner, M.D.; Presidential Committee, V. L. Orsen, M.D., M. Calkins, M.D., S. F. Pomeroy, M.D., A. R. Rice, M.D. The objects of the society are, the cultivation of confidence and good-will between the members of the profession, and the eliciting and imparting information upon the different branches of medical science, and the establishment of a museum and library of pathological anatomy.

DR. TRIQUET, the distinguished writer on aural surgery, in Paris, died in January of this year, in the forty-third year of his age.

DR. WM. M. NICKERSON, Del., has been confirmed by the United States Senate as Assistant-Surgeon, United States Navy.

Original Communications.

SOME POINTS IN THE

ANATOMY AND PHYSIOLOGY OF THE SKIN,

AND IN THE SO-CALLED SYMPATHIES; BEING THE SUBSTANCE OF TWO LECTURES DELIVERED BEFORE THE NEW YORK MEDICAL JOURNAL ASSOCIATION.

By CHARLES E MORGAN, A.B., M.D.,

PHYSICIAN FOR DISEASES OF THE SKIN AT THE NORTHERN DISPENSARY, NEW YORK CITY.

The skin consists of—1. The external, non-vascular epiderm, or cuticle (ecderon of Huxley).—2. The *papillated*, neuro-vascular *corium*, or true skin (enderon of Huxley); and 3. The subcutaneous areolo-fatty tissue containing the sweat and sebaceous glands and the hair follicles. The *epiderm* consists again of two layers, an external or horny layer (stratum corneum), formed of flat, polygonal, usually nucleated epithelial scales adhering strongly together by their margins and surfaces, so as to give rise to nearly parallel strata or laminæ. 2. An internal layer separating this from the next one (the rete Malpighi), and perhaps really the oldest cells of the latter, though running parallel with the former, is made up of flat but nucleated cells. Here it is where the horny stratum is regenerated and where pathological processes usually begin.

The *rete* Malpighi, at its upper part, consists of large distinctly nucleated cells studded over with points like a chestnut-burr, and hence their name of spinous or dentated cells, or from their discoverer, cells of Schrön. As we go further down, the cell-walls become less and less distinct, until finally we may get only very small nuclei, having a more or less regular arrangement, and imbedded in a finely granular substance—the *intermediar membrane* of Henle. Between this membrane and the substance of the papillæ is a structureless band called by Todd and Bowman, from its situation, the *basement membrane*, but considered by Krause to be simply the optical expression of the delicate crenation of the surface of the papillæ.

The *papillæ*, or conical bodies, constituting the external surface of the derm or corium, are, like the latter, formed essentially of connective and elastic tissue, and are divisible into: 1. The *vascular*, containing a capillary loop and generally a terminal lymphatic blind cul-de-sac; and 2. The *nervous*, containing a peculiar sensitive nerve termination called from its position *axile body*, its supposed function *tactile body*, and its discoverer *body of* Meissner: only exceptionally does the same papilla contain a capillary loop and a tactile body; and everywhere the vascular papillæ rise above the less numerous nervous papillæ. The tactile body is oval in shape, with irregularly indented outlines, and formed of a thick, firm, and resistant cell-wall of connective tissue, with elongated nuclei arranged transversely as a rule, and softer cell-contents of a clear, finely-granular amorphous matter. In some cases, however, I have detected another tunic with nuclei arranged longitudinally, that is, parallel to the axis of the body, and most internally a structureless membrane completing the resemblance to an aborted hair-follicle, as Kammler first surmised it to be. One or more double-contoured nerve-fibres rise up to the bottom of the body and there pierce it, or else do so at the top after having wound spirally around the body to this point, and leaving the nucleated neurilemma behind, terminate in the softer cell-contents in one or more pale axis cylinders. In the papillæ of the conjunctivæ, the lips, glans penis, we have the so-called *club shaped bodies* of Krause, consisting of a thin, nucleated cell-wall, containing a transparent, finely granular mass, in which a sensitive nerve-fibre losing its double contour ends in a single pale axis cylinder, or in a convoluted mass. In the subcutaneous areolo-fatty tissue along the sides of the fingers and in the palm of the hand, the sensitive nerves often terminate in the bodies of Vater or Paccini. Each such body consists essentially of a Kraussian body situated axially and surrounded by numerous concentric layers of nucleated connective tissue, making a kind of capsule for it.

The *sweat* gland is divisible into the glomerulus or glandular coil, and the excretory duct. The glandular canals consist of an external tunic—of indistinctly fibrous connected tissue with scattered elongated nuclei—lined internally by a finely granular tunica propria, covered internally by a single or multiple layer of polygonal epithelial cells. The large glands of the axilla possess, in addition, a middle coat of smooth muscular fibres running parallel with the axis of the tube. The coils of the glomerulus are bound together by areolo-fatty connective tissue in which ramify numerous capillaries. The excretory duct, whose diameter is always inferior to that of the glandular canal, though consisting essentially of the same elements, pursues a slightly wavy course from the upper part of the glomerulus up to the rete Malpighi, where, reduced to its epithelial lining, it dilates to twice its previous size, and after making two to sixteen spiral twists terminates on the surface of the epiderm in the small, round, often funnel-shaped opening called the sweat-pore. According to Sappey there are 700,000 to 800,000 sweat-glands; but Erasmus Wilson makes out 7,000,000 in the adult man, and estimates the total extension of sweat tube at nearly twenty-eight miles.

The *healthy sweat* is a thin, colorless liquid, somewhat troubled by the particles of epithelium suspended in it; of somewhat saline taste and acid reaction, except where large quantities have been given off, and in the case of that of the axillæ, the sole of the foot and between the toes, the inguino-scrotal and vulvar regions, etc., where it is alkaline. The human sweat contains water, ameisenic, acetic, butyric, propionic, and occasionally baldrianic (v. valeric) acids, the chlorides of sodium and potassium, the alkaline sulphates and phosphates, the earthy phosphates and oxide of iron, the usual salts of the blood. Occasional ingredients are ammonia, the hydrotic or sudoric acid of Favré, alkaline lactates, and various pigments not thoroughly studied.

In 1000 parts.

	Urine. (J. Vogel.)	Sweat. (Favré.)
Water	960.0	995.573
Solid matters	40.0	4.427
Urea	28.0	
Uric acid	0.5	
Chloride of Sodium	11.0	2.780
" " Potassium		0.748
Alkaline Phosphates	3.2	} traces.
Earthy Phosphates	0.8	
Alkaline Sulphates	2.0	0.011
" Carbonates		0.016
Ammonia		
Alkaline Lactates	4.0	0.317
" Sudorates		1.573
Fatty matters		0.013
Creatine, Creatinine, Xanthine, Hypoxanthine, Oxalate of Lime, Uro-hæmatine	In small quantities.	

On comparing Favré's analysis of the sweat with J. Vogel's of the urine, we find that in both excretions the quantity of water is large, but in the urine there

are more solid matters than in the sweat, more urea, sulphates, and phosphates, but relatively less chloride of sodium; and while having exclusive possession of the uric acid, creatine, creatinine, oxalate of lime and urohæmatine, it has no lactates, or sudorates, no ameisenic, acetic, propionic, butyric, and baldrianic acids. In uræmia, especially that due to Bright's disease or cholera, urea is largely present in the sweat. In diabetes this excretion contains sugar; in rheumatic gout uric acid as urate of soda, but never albumen; and the stickiness of certain sweats occurring as a grave symptom in phthisis, cholera, typhoid and puerperal fevers, is due to no known substance. In icterus the bile-pigment colors the sweat, tears, and urine dark yellow; and in rare instances blue, green, red, black, and even phosphorescent sweats have been observed. Benzoic, hippuric and tartaric acids, when taken internally, pass rapidly into the sweat, whereas salicine and quinine do not at all, and iodide of potassium requires some five days to do so. The coloring matter of rhubarb; certain odorous principles like asafœtida, musk, garlic, onion, leek, etc., when taken freely, taint the sweat, and so, too, do certain medicines such as cantharides, valerian, camphor, iodine, sulphur, phosphorus, tellurium, etc.

The kidneys are as it were closely compacted bundles of sweat-glands placed along the course of one of the largest arterial streams of the economy, and secrete continually, whilst the sweat-glands are minute kidneys scattered irregularly over the surface of the body on the terminal divisions of the aorta, and only secrete occasionally. To complete the parallel both these apparatuses are subjected to the influence of the nervous system. Thus, while fear causes the breaking out of a profuse sweat, hysteria gives rise to an abundant flow of a pale urine of low specific gravity. Again, when the kidneys act without energy, as during active exertion in the summer of dry, warm climates, during the existence of a low barometric pressure, the sweat glands instead of discharging, as is usual, but 500 grammes a day, may pour out 2,650 grammes in an hour and a half. Lastly, diaphoretics may act as diuretics or *vice versâ* according to the manner in which they are used.

The skin is also an organ of respiration absorbing oxygen and exhaling carbonic acid; the proportion to that escaping from the lungs being, according to Scharling, as 0.0089 to 0.012.

The *sebaceous* glands are not follicles but simply grouped glands, occurring generally in connexion with the hairs, though largest where these are smallest, as on the nose. These glands consist of a homogeneous, transparent, finely granular *tunica propria*, lined by polyhedric epithelial cells, never normally nucleated, and filled with minute oil drops which, escaping on the rupture of the cell, help to form the sebaceous matter. The latter, examined microscopically, is seen to re-

In 100 parts.

semble milk very closely; indeed their chemical compositions are nearly, if not quite, identical as here seen, and many facts tend to prove that the sebaceous glands are really rudimentary milk glands scattered over the surface of the body; and that the ceruminous glands in the external auditory meatus are a further transition than the sweat glands of the axilla into the sebaceous glands, just as the mucous glands of the mouth, etc., are the connecting link between the sebaceous and the sweat glands in the other direction.

The sense of TOUCH, in its widest acceptation, implies our consciousness of all the sensorial impressions which are neither visual, auditory, olfactive, nor gustatory; whereas in its limited application it signifies the modification of the general sensibility restricted to the skin and enabling us to form definite ideas of the size, number, weight, temperature, and consistency of the bodies we are brought in contact with. Evidently, then, even in this limited sense touch is a complex phenomenon, and hence it was that E. H. Weber subdivided the tactile impressions according to their causation into:

The sense of *tactile discrimination* or *localization*—that is, the power enabling us to distinguish between two similar sensations excited simultaneously in two different points of the skin, and to ascertain in a measure, not only their distance apart, but also their relative situations. In 1829, Weber discovered that when the points of a pair of dividers or compasses, guarded by bits of sealing-wax, were applied to the skin, the eyes being closed, they were not felt as distinct separate points unless the *inter-compass point distance* (Dr. Graves's limit of confusion) had a certain value which varied in different regions of the body. Thus, on the tip of the tongue it was only one-half Paris line or one twenty-fourth of an inch; on the finger-tip one line, and on the trunk, forearm, and thigh, thirty lines. This delicacy of perception is greatest in the direction of the distribution of the nerves. Thus, on the middle of the forearm the points are felt as separate when two inches apart if placed transversely, but scarcely so at three inches if in a line parallel to the long axis of the limb. When two points, applied simultaneously to the skin, are clearly distinguished, the separating distance seems to increase with the acuteness of the tactility in the front of the surface under examination. Hence, if the points of the compass, while separated by two or three lines, are applied to the cheek just in front of the ear, and then moved gradually towards the angle of the mouth, the points seem to recede from one another in consequence of the increase in tactile acuteness. When the two points are applied, not simultaneously, but in succession, they seem further apart, and, up to a certain limit, all the more so the longer the interval between their successive applications. The same seeming increase is observed when the points are applied simultaneously to different sides of the median line; or on parts like the two lips or eyelids, whose relative position is not constant; or, as is the case with the palmar and dorsal surface of the fingers, whose structure and function are different. Valentin found furthermore, that while the absolute delicacy of touch varied in different persons, the relative delicacy was constant in the same parts of the same person. Children, owing to the greater crowding together of the sentient points; women, on account of the softness, smoothness, and greater vascularity of their skin; and the blind, in consequence of great practice and from concentrated attention, have a very delicate sense of touch. R. Lichtenfels discovered that the use of atropine, daturine, morphine, strychnine, and alcohol, blunted this power, enlarging the *circles of perception* or *areas of confusion*, mapping off the surface of the body into an irregular mosaic; and Wundt and Bertheau finding this to be so during the progress of certain cases of paralysis, proposed to use Weber's com-

passes as an æsthesiometer. Volckmann remarked next that by incessant practice the limit of confusion could be reduced to one-half or one-quarter of its primitive value, and, as Weber observed, this increased delicacy actually extends to the part which, though actually unexercised, is situated symmetrically, e. g. from the left to the right thumb.

1. The *Sense of Temperature* arises when the acting body is hotter than the normal heat of the human body; beyond a certain limit in either direction, a burning pain is produced, as is the case when a very cold or a very hot metallic body is handled. Our discrimination of temperature is affected by the rapidity of the changes, the extent of skin surface involved, its thinness and richness in nerve-terminations and vessels. In the following series established by Weber, the most sensitive parts come first: the tip of the tongue, the eyelids, cheeks, lips, neck, trunk, etc. Owing to the thinner epiderm and more extended surface, water, which feels quite hot to the legs, is readily supported by one finger unless it is moved about. For cold water seems colder, and warm warmer, when the hands are moved in it, than when they are kept motionless, in the latter the water acquiring the heat of, in the former case communicating its own temperature to the skin. As in the similar case of tactile discrimination, the left hand and side, having a thinner epiderm generally, have a more acute power of appreciating temperature than the right, and in either case practice and concentrated attention refine the sense very much. According to A. Fick and Wunderli very feeble tactile and temperature excitations may very readily be confounded with one another. Ritter discovered under certain circumstances the action of very strong galvanic currents on the skin excited during their continuance, or at the instant the circuit was completed or interrupted, a sensation of either heat or cold as the case might be.

2. The *Sense of Weight*, or *Pressure*, is the power to estimate the amount of a force compressing or stretching the skin during the total absence of any muscular action, i. e. of what is termed the *muscular sense*. Weber found that he could distinguish between two weights bearing to each other the ratio of 19.2 to 20, or even 29 to 30, when laid on the finger-tips, whereas on the middle of the forearm the ratio had to be 18.2 to 20, and on the brow 18.7 to 20. The delicacy of this estimation is much greater when the impressions are *successive* than when they occur simultaneously, provided that the separating interval does not amount to forty seconds, though it may to twenty. According to Kammler the least weight perceptible on the finger-tip is 0.005 to 0.015 gramme; but on the finger-nail one gramme, that is fifteen grains. There is a certain relation between the sense of temperature and that of weight. Thus, Weber found that cold bodies seemed heavier than warm ones of actually the same weight. The *Muscular Sense*, in conjunction with the sense of pressure, enables us to form accurate conclusions as to the weight, consistency, resistance to rupture or overturning, etc., offered by the bodies we are handling. Thus, a truncated cone set with its small end on the hand laid passively on a cushion, feels heavier than when its large extremity is thus placed, whereas on poising it in the hand no such error is committed.

In the general use of an anæsthetic at first there is increased cutaneous irritability, succeeded by analgesia; the patient sees and feels the cutting of the knife, but suffers no pain, and his muscular sense is still active. Later voluntary and reflex action cease and organic etherism comes on, marked in the beginning by the lowering of the animal heat, then by stoppage of respiration and hæmatosis, and lastly by death supervening on paralysis of the heart. The return to the normal state obtains in the same order, but reversedly.

Kraue, while agreeing with Weber that the superficially seated bodies of Meissner are for the perception of temperature, chiefly though not exclusively, affirms in addition that the more deeply situated bodies of Paccini are for the sense of weight, and the hairs for that of localization and the detection of mere contact. Thus Aubert and Kammler remarked that pressure, to be perceived, must be greater on a part that has been shaved than on one that has not, and in fact they considered the tactile bodies to be aborted hairs. Mr. Broughton found that while a kitten could readily thread blindfold its way out of a maze, in which he had designedly placed it, as long as its whiskers were intact, it utterly failed to do so when these were shaved off. Spiess, Aubert, Kammler, Schiff, &c., believe that the muscular sense is really situated in the skin, and Krause that the bodies of Paccini are the organs mainly concerned in it. Brown-Séquard, however, has shown that while the sensitive nerve fibres, giving rise to the other senses, cross in the spinal cord, those regulating the muscular sense cross in the medulla oblongata like the other motor nerve-fibres. Calmeil, Bouillaud, Gerdy, Flourens, and Longet, have shown that the removal of the two cerebral-lobes does not impair the general sensibility; while Flourens and Brown-Séquard, in opposition to Gerdy, Bouillaud, and Longet, assert that in this case, the power to perceive impressions is abolished, so that the spinal cord is not a true sensorium.

In foot-sleep, the touching of the limb causes an unpleasant prickling and quivering, like a feeble induction shock, and the same occurring in hemiplegia we see why the rubbing in of ointments is here so disagreeable. As Leyden remarks, Weber's method was intended to measure the delicacy of tactile discrimination and not the degrees of alteration of the sense of touch, which consists of two elements—the locality feeling and absolute sensibility—having no definite and constant relation to one another. Thus, when disease advances slowly, the locality feeling, being so largely a thing of practice and attention, may remain intact, though the psychological impression it excites may, from want of absolute certainty, be only a more or less clever guess. Hence, in pathological cases we must measure not only the locality feeling, but also the degree of absolute sensibility. Puchelt was the first to describe what is styled *partial sensitive paralysis*. He found cases in which the temperature sense was intact, while that of tactile discrimination was much impaired. Eigenbrodt remarked that patients suffering from mechanical or pathological alterations of the spinal cord, had lost the sense of weight. Lastly, Leyden discovered that in grey degeneration of the posterior columns of the spinal cord, while the muscular sense, owing to the integrity of all the motor apparatus, was intact, and the sense of temperature nearly if not completely so, the absolute sensibility was much impaired.

Hyperæsthesia, then, is the peculiar state in which the absolute sensibility is increased—the minimum of stimulation needed to excite perception being less than normal. *Hyperalgesia* is where stimuli which normally cause only a slight sensation, give rise to pain in consequence of the lowering of the pain minimum. Sometimes the minima of perception and pain coincide together, in which event the first is lowered, while the second remains normal. This *relative hyperalgesia* is quite common in disease of the spinal cord. *Positive* hyperalgesia also probably occurs in neuralgia, hysteria, injuries of the spinal cord, etc. *Retarded nerve conduction* also obtains in grey degeneration of the spinal

cord, but has yet to be studied. Lastly, we have what may be termed the *sense of direction*. The tactile sense, when operating by itself, and not corrected by the sense of muscular effort called forth to antagonize it, always suggests the idea that pressure is made vertical to the surface. Thus it is that when the hair of the head is pulled, we know the direction of the traction. But if we hold the head of the person operated on steadily between our knees, and prevent the traction from calling forth the muscular action of the scalp, by pressing firmly with the fingers around the point from which the hair is pull d, the patient cannot tell from what direction you pull his hair.

The interpretation put by our minds on tactile impressions, is in part the result of intuition and in part that of practice. Thus, intuitively we refer the impression made on any part of a sensitive nerve, to its peripherical expansions, or (as in the case of amputated limbs, etc.) to the regions in which these should normally be situated.

Leaving our present topic, we next pass on to the consideration of the so-called *sympathies*.

One of the most important attributes of the nervous system, is that of—1. Linking together the different tissues endowed with the properties of animal life, through the interposition of the nerve-centres—the impression carried thither by the *peripherical, incident, or eisodic* nerves being handed over in a new physiological or psychological form, to the *excentric* or *exodic* nerves—the whole constituting Marshall Hall's *diastaltic arc*—the summit of which is the nerve centre. 2. That of linking together the organs of vegetative life by themselves, or else with those of animal life; the spinal cord being the centre and the great sympathetic the branches of the diastaltic arc. The transference in the grey matter of the spinal cord through the intervention of the nerve-cells, of the irritation brought there by one sensitive nerve-fibre to another of the same kind, is called *co-sensation* or irradiation; while that passing from a sensitive to a motor nerve-fibre, or *vice versâ*, is termed *reflex action* (motion or sensation, as the case may be), and from a motor to a motor nerve *association of motion*. *Reflex actions* (of Prochaska and *excito-motory* of Marshall Hall) are divisible into: 1. *True reflex* or *diastaltic* actions, or those belonging in particular to the organs of animal life: 2. *Organic* or *sympathetic reflex actions*, or those appertaining to the organs of vegetable life (nutrition and reproduction).

Sympathies are then reflex actions in which an inconscient impression, transmitted in general by the branches of the great sympathetic to the spinal cord, gives rise there to an involuntary motor action, carried to other regions by motor nerve-fibres generally divided from the sympathetic, though sometimes also from the nerves of animal life. This motor incitation transmitted to the smooth muscular fibres of the blood-vessels of the part, or to those of the excretory ducts of glands, or to those of the walls of the intest nal tube or of the heart, gives rise to diverse interesting phenomena.

All the organs and living tissues have a mutual and regular coördination, so that one part is weakened by the increased action of another, i. e. normally, equilibrium of action obtains. In addition, each of these organs or tissues exerts on one or more other parts, a special influence more marked and frequent than that common to the rest of the economy. This is what is termed the doctrine of *territorial influence*, or of the *neuro-vascular areas*. If this reaction of one organ or tissue on another obtains by the exercise, and for the accomplishment of their respective functians, it is termed *synergy* or *coöperation*, as in the case of the glans penis and the testicle during coition; whereas, if this occurs between two organs not having any direct physiological relation, it is styled *sympathy*, as is seen when sneezing results from a strong irritation of the retina. Now we have sympathy:

1. Between the different parts of an organ or tissue, and this explains the spreading of an erysipelas from one part of the skin to another; and the changing of a coryza into a pulmonary catarrh, or a diarrhœa, etc.

2. Between paired organs. Thus, when one eye is diseased, the other, though not directly acted on, is soon involved by sympathy, and the same is true of the two ears, lungs, kidneys, etc.

3. Sympathy between one organ and another of the same apparatus. When the uterus, as in pregnancy, takes on increased activity and development, this reacts on the mammæ and sebaceous glands. In fact, the secretion of milk is the effect of the normal or pathological excitation of the genital apparatus. Thus, in man it occurs when there is sarcocele, or other diseases of the testis. Again, acne, which is a disease of the rudimentary milk-glands, the sebaceous follicles, obtains mainly during the period of great genital activity. The French term them *boutons de sagesse*, or pimples of chastity; and they generally disappear after marriage. According to J. Frank, though the skin of eunuchs soon acquires the wrinkles and sallowness of old age, they enjoy a remarkable immunity against cutaneous affections.

The nerves of mucous membranes are generally derived from the sympathetic, except where skin passes insensib'y into mucous membrane; and here alone is it that ordinary sensibility exists. Thus, the urethra, except in disease, is not very sensitive beyond the glans penis, and the rectum beyond the anus. The greater sensitiveness of the orifice as compared with the rest of the mucous membrane with which it is in such close sympathy, is very available for counter-irritation in the treatment of various affections of the mucous membranes and their annexes. Thus it was that Bichat proposed to treat ophthalmia rather by producing an artificial coryza than by blisters or setons to the neck or temple. Similarly, we have the treatment of cutaneous diseases by purgation, excessive costiveness being so often a prominent feature in them; and the relief of toothache by placing an irritant in the external auditory meatus. Again, Brown-Séquard has shown that the sudden introduction of cold water into the external ear excites an epileptiform convulsion; and we know how that sometimes epilepsy is associated with dental caries, and that certain shrill sounds excite the sensation called *setting the teeth on edge*.

4. Sympathy between an organ of one apparatus and that of another. Thus during digestion, while the gastric and intestinal glands are most active, the sweat-glands, according to Sanctorius, are nearly inert. Again, when a cold body enters the stomach at a time when the skin is bathed in sweat, the sweating soon ceases; whereas warm teas favor sweating. Tickling the soles of the feet sometimes causes nausea, and even syncope; and Bichat thought that in hemiplegia, or hypochondriasis, etc., it was possible, by repeating the tickling several times a day, to get a stronger and more enduring effect than the merely temporary one following the use of blisters, especially as, unlike the latter, it acts exclusively on the nervous system. Now, as the action of the surface is diminished when there is internal inflammation, by increasing the action of the former, we remove or lessen that of the latter, and hence the use of counter-irritation. However, issues do no good unless somewhat painful or in the condition of healthy ulcers. Nevertheless, the issues should not be too painful, nor kept active too long; for after they have removed the

inflammatory action below, they still combine to act on the parts, lessening their action; and thus stop or impede the proper operation of the healing process.

Lastly, it has long been known that when any particular action disappears suddenly from a part, it will often quickly affect that organ which is most in sympathy with the part or organ originally diseased. Hence it is, why the spontaneous appearance of an extensive eczema often coincides with a favorable change in phthisis, and its disappearance (so called *retro-cession*, or *repercussion*, or *driving in*) with an unfavorable one.

These facts show how it is that the knowledge of the special sympathies between different organs and tissues explains the causation and location of disease, and shows where remedies are best applied.

NITROUS-OXIDE AS AN ANÆSTHETIC, WITH REPORT OF SEVEN CASES.

By CHARLES F. TAYLOR, M.D.,

NEW YORK.

The recent death, at Bellevue Hospital, of a patient while under the influence of chloroform, occurring, as it did, without the omission of any precautions, and in spite of the most intelligent and persistent efforts to sustain animation, will no doubt have a tendency to deter a still larger number of practitioners from the use of chloroform as an anæsthetic. But an anæsthetic we must have. The ability to annihilate pain and prevent muscular action during surgical operations is an incalculable blessing to the world, and it were even better to run all the risk there may be in the use of chloroform than to attempt to get along without anæsthesia. Ether has some serious objections. It is very unpleasant, especially to children; is frequently slow to act, and sometimes is impotent altogether to produce insensibility without carrying it to an imprudent degree. Besides these objections, though considered entirely safe, it often leaves the patient in a state of great prostration.

Under these circumstances, I have thought that my experience in the use of nitrous-oxide as an anæsthetic might be of some interest at this time.

Case 1.—This was an operation for anchylosis of the hip-joint. Tenotomy and very strong efforts to extend the thigh were made, occupying about five minutes—the patient, a girl of thirteen years, being in complete anæsthesia, and in as favorable condition as could be asked. She was brought under the influence in about one minute, and passed out of it in about the same length of time. No ill effects followed.

Case 2.—This was a simple operation to extend the knee by dividing the tendons of the hamstring muscles. It was chiefly remarkable for the rapidity of the whole operation, the little patient, a boy seven years old, not being quite two minutes unconscious.

Case 3.—This was an operation for deformity of the hip-joint, in a lady of twenty-two. In this case our attempts to produce unconsciousness by the use of ether—carefully administered by Dr. Vermilye—were unsuccessful. The most persistent efforts for over one hour failed to produce the desired effect. We found afterwards that the ether used was not good, but the quantity given was very great. Again we resorted to the nitrous-oxide, and in about forty seconds there was complete anæsthesia. The operation, which was division of the sartorius, occupied one minute, and in thirty seconds more the patient was as well as if nothing had happened.

Case 4.—This was a very interesting case of so-called "hysterical joint," affecting the shoulder, in a very susceptible lady, followed by partial anchylosis. Three years before, I had operated on the right shoulder, assisted (as in the case first related) by Dr. Peaslee, but there was such complete prostration afterwards from the ether, that she was confined to the bed for more than a month, and it was fully two months before she recovered from the shock. Three years afterwards I was sent for to perform another operation for the same trouble, which had returned this time in the *left* shoulder. The dread of the operation, or rather of the effect of the ether, was so great, that it had been put off till all motion at this joint had ceased, though the adhesions were readily broken up. But the prostrating effects of the anæsthetic were even greater than before, and she was not able to get up from her bed till nearly all the benefits of the operation had been neutralized by the long confinement. When, at last, she did get up, she was so pale and feeble that I abandoned the idea of employing ether, and again resorted—after unsuccessfully endeavoring to get along without further operation—to the nitrous-oxide. The success was all that could be desired. There was no prostration whatever following the operation, and the next morning she came down to breakfast, feeling as well as ever.

Case 5.—About a week afterwards I again operated on the same case, with the same happy escape from the prolonged prostration which had invariably attended the use of ether.

Case 6.—This was a case of deformity, requiring division of the flexors of the thigh, in a feeble girl of nine years of age. It was rapid, and not attended or followed by the slightest shock or unpleasant symptoms.

Case 7.—This was an operation for club-foot, and like the previous case, was characterized by the completeness of the anæsthesia and the absence of all ill effects following it.

In the first five cases the gas was administered by G. R. Colton, by means of a large rubber bag, with a single mouthpiece, the expired breath being thrown into and mixed with the gas in the bag, which formed the next inspiration. Although the administration of the gas was successful as above related, yet I was always anxious about the venous, partially asphyxiated appearance of the patient, which made us cautious about using it in operations requiring much time. This appearance I believe to be due more to the imperfect method of administering the gas than as inseparable from this method of producing anæsthesia. Accordingly I embrace an early opportunity of employing a method devised by Mr. Blakeney, a physician in Twenty-second street, near Sixth avenue, which entirely avoided breathing over any of the expired gases. His method consists of forcing the gas forward under pressure through a tube, with a valve which opens on inspiration and closes on expiration, and the breath passes out through another tube in the open air. In fact, the patient breathes pure gas all the time. Although there seems to be no danger from the former, yet I greatly prefer the latter method, and shall henceforth employ it. It will be seen that I have no experience as yet in nitrous-oxide as an anæsthetic in operations requiring more than five minutes to perform.

To sum up, I would enumerate the following advantages of nitrous-oxide over ether, viz. 1st. The rapidity of its action, causing the saving of time to physician and patient; 2d. Its agreeableness; 3d. The speedy passing off of its effect; and 4th. The absence of all after effects of sickness at the stomach, vomiting, headache, etc. Not one of all those cases complained of any unpleasant symptom whatever. Its disadvantages are—1st. The inconvenience of not always having it at hand when wanted; 2. The cost ($5.00) of having it brought to

you; and 3d. Its possible insufficiency or danger in prolonged operations. But for all short operations I believe nitrous oxide to be the best anæsthetic we have.

For all superficial operations, such as the opening of abscesses, etc., I have found Richardson's vaporizer to be amply sufficient.

AN ILLUSTRATION OF THE BENEFICIAL EFFECTS OF

ATOMIZED LIME-WATER IN MEMBRANOUS CROUP.

By H. ERNEST SCHMID, M.D.,

WHITE PLAINS, N. Y.

On the 22d of last November, I was called some three miles from my residence to see a little child, about 20 months old, who had been suffering with croupal symptoms for five or six days. Very slowly and gradually had they come on, so as not to give the mother any uneasiness; but had increased in intensity, day by day, in spite of the various remedies applied, until the child presented the alarming spectacle which had induced the parents to call me in, and which at once indicated a case of membranous croup, of the gravest aspect.

I ordered immediately the constant inhalation of the vapor of hot water and Dr. Leaming's mixture of chlorate of potassa, muriate of ammonia, senega, etc.

When I paid my second visit, on the following day, the little boy was evidently more comfortable. He had coughed up a large piece of false membrane, and the shrill, brassy inspiration was materially softened.

Becoming engaged in an obstetrical case of uncommon severity, I was unable to see my little patient again until forty-eight hours later. I found him then in an almost hopeless condition. His labored breathing could be heard outside the house. He had grown so unruly that his nurses had ceased to apply the steam, and were awaiting with resignation his death, which seemed speedily approaching. He lay with his head thrown far back, his lips deeply cyanotic—in fact, his entire surface showing in its dusky hue the fearful extent of the deficiency of arterial blood, his pulse small, and beyond counting.

I had seen the piece of membrane, coughed up by the child on the second day of my attendance, dissolve in lime-water as readily as any diphtheritic deposit; and I determined now to give the little sufferer, as a last chance, the inhalation of atomized lime-water. In fifteen minutes from the time I had begun to let the spray play over the mouth and nose of the child I perceived, with heartfelt satisfaction, that my efforts were beginning to be crowned with success. The harsh, metallic breathing grew softer, and at last melted down as if hushed by a magical power, the cyanotic hue gradually disappeared from the face, and before I left the house a moribund condition was exchanged for one of hopeful expectation. A relay of nurses kept up the lime-water spray, without ceasing, the rest of the day and the following night, so that, to my extreme gratification, I found my little patient, on my visit early the next morning, sitting up in his cradle, quite contented with the supply of air drawn in through his nostrils. It was now more difficult to make him breathe the spray. I exhorted the attendants, however, to the utmost perseverance, and left, delighted with my success thus far. But, on the following day, I found almost as bad a state of things as at my first visit. The glass tubes (of the spray-producer) had become choked up by the deposit of lime from the lime-water, and would work no more; the child had thus been without the spray for at least eighteen hours, the parents not taking the trouble to inform me at once of the fact. I hastened back to my office, substituted india-rubber tubes for the glass,—the former having a much larger bore,—returned to my little charge, and again had the satisfaction of procuring him speedy amelioration of his urgent symptoms. From this time he steadily improved, and, after the persevering use of the atomizer for three more days, I dismissed him from my list perfectly cured.

FEBRUARY, 1867.

ADVENTITIOUS GROWTHS OF THE UTERUS.

NEW FORMATIONS OF CONNECTIVE TISSUE.

(Being a Translation from the German of "Klob on the Pathological Anatomy of the Female Sexual Organs.")

By JOSEPH KAMMERER, M.D.,

AND

B. F. DAWSON, M.D.

NEW YORK.

The new formations of connective tissue which take place in the substance of the uterus are developed from its interstitial tissue, and in their growth affect either the whole extent of the latter, or isolated portions of it, in a diffuse manner; or these new formations, becoming independent, are situated under various circumstances in circumscribed portions of the uterine substance; or, lastly, they are considerably separated from the rest of the tissue of the organ. According to these different relations to the parent tissue, these varieties of new formation of connective tissue must severally be considered.

DIFFUSE GROWTH OF CONNECTIVE TISSUE IN THE UTERUS, ENGORGEMENT, CHRONIC INFARCTUS OF THE UTERUS (*Kiwisch*).

In consequence of formative irritation, especially when it has existed for a long time, the whole uterine connective tissue sometimes proliferates either without accompanying increase of the muscular substance, or, if this does occur, the connective tissue predominates to such an extent that the muscular substance is comparatively of not much account. By this process, an increase of the substance of the uterus is produced by a portion of its tissue which, as regards function, cannot be considered as the most essential to the organ. I therefore do not hesitate to classify this affection with the qualitative alterations of formative irritation, inasmuch as the natural proportion of the normal tissues constituting the uterus is thereby considerably altered.

In this disease the uterus is uniformly increased in its diameters, though not always in all of them; its body and fundus generally assume a spherical shape, and frequently attain to the size of a man's fist, and even larger. Its walls are sometimes considerably increased in thickness, up to twelve or fifteen inches, especially the posterior one and the fundus. The cavity of the uterus is absolutely enlarged, chiefly elongated; but the uterine walls lie close together, and an increase of its cavity, in the general meaning of the term, is only met with in rare instances; I should rather say that the cavity of such an hyperplastic uterus was relatively smaller than that of a normal one. Exteriorly the fundus uteri appears rounder and broader, the anterior and s ill more the posterior walls thickened, the latter even vaulted or of the shape of a boat's keel, the cervix more ample and increased in substance, and the vaginal portion broader and thicker.

The condition of the parenchyma of the uterus varies according to the duration of the disease. In the first stages it is more succulent and turgid, owing to the immatured condition of the newly formed connective tissue. The longer the duration of the disease, the more

is the mucous connective tissue transformed into the fibrillary variety, accompanied with contraction of tissue; the parenchyma on section appears white, or of a whitish-red color, deficient in blood-vessels from compression of the capillaries by the contraction of the newly-formed connective tissue, or from partial destruction or obliteration of vessels during the growth of tissue; the firmness of the uterine substance is increased, simulating the hardness of cartilage, and creaking under the knife. The newly-formed tissue is chiefly composed of thin fibrils, deficient in nuclei, which cross the uterus in lines of various breadths in all directions, forming a complicated felt-like network, and constituting the greater substance of the uterus. In the first stages of the disease the muscular fibres are broader and hypertrophied, but at a later period may be completely lost in the proliferation of connective tissue.

The causes of this diffuse growth of the connective tissue must be sought for in habitual hyperæmia, and I cannot concur in that explanation which interprets the process described as chronic inflammation. It is true that inflammatory derangement of nutrition is often followed by proliferation of connective tissue, but it is impossible to conclude that from the continuance of this formative irritation, derangements of nutrition are produced, the essential characteristics of which are destructive.

Diffuse growth of connective tissue constitutes the so-called induration hitherto considered as a result of parenchymatous inflammation of the uterus.

Frequently, however, this proliferation of connective tissue is developed after repeated deliveries in rapid succession, without any previous or existing inflammation; it also occurs in many displacements of the uterus, especially those in which venous reflux is hindered, in consequence of traction of the uterine appendages. When tumors exist, especially fibrous, proliferation of connective tissue almost always coexists in the rest of the uterus. When the uterine cavity is distended by accumulated mucus or menstrual blood, this proliferation generally exists in the form of eccentric hypertrophy. Finally, it is often combined with the various tractions to which the uterus is subject, and sometimes is developed in consequence of the puerperal condition.

From the description of this affection, it is evident that the term "infarctus," used by some gynocologists, is absolutely improper. For reasons mentioned, I would also advise the disuse of the term "chronic inflammation."

In most cases, the mucous membrane of the vagina participates in the chronic irritation; we frequently find it in a state of epithelial desquamation, and even of catarrh and blennorrhœa. The peritoneal covering of the uterus is generally thickened and covered with various-shaped false membranes. The pampiniform and utero-vaginal plexuses are often in a varicose condition, and this is not only caused by the contraction of the newly-formed connective tissue, and consequent occlusion of the blood-vessels, but is also frequently the consequence of the same cause which produced the diffuse growth of the above tissue.

Besides local hyperæmia, we must take into consideration the general causes of this affection; thus it is often found complicated with diseases of the heart. Scanzoni calls particular attention to the fact that proliferation of connective tissue repeatedly occurs after successive miscarriages, and is also said to occur in prostitutes.

When diffuse growth of the above tissue does not take place uniformly in all parts of the uterus, hyperæmic distension of its blood-vessels is apparent in those portions not at all or only slightly affected, and in these parts extravasations may occur, especially in the external or internal layers of uterine tissue (Scanzoni).

The consequences of the above-mentioned pathological conditions are derangements of menstruation and sterility. As regards their termination, it must be noted that in the majority of cases the proliferation gradually ceases after attaining a certain degree, and no further alterations of tissue take place. In other cases, at the climacteric period, involution occurs, commencing generally by distension of the uterine cavity, with an accumulation of mucus. What has been said by various authors on the relations of diffuse growth of connective tissue to the development of carcinoma, must be considered as a mere hypothesis; this same question has been raised in regard to other organs in which carcinoma is developed from an hypertrophy of tissue, and in a great many cases it must be left to the discretion of observers whether they will classify certain cases with carcinoma.

In the preceding description I have only spoken of that proliferation which uniformly affects the entire interstitial connective tissue of the uterus; we shall next consider the equally important *analogous* conditions which only affect portions or layers of the uterus.

Original Lectures.

SCROFULOSIS AND TUBERCULOSIS.

BEING A LECTURE BEFORE THE CLASS OF

THE JEFFERSON MEDICAL COLLEGE.

SESSION 1866–7.

BY S. H. DICKSON, M.D.,

PROFESSOR OF THEORY AND PRACTICE OF MEDICINE.

PART II.

FROM what has already been said, we can account for scrofula very extensively; but there is a certain prevalence of scrofula difficult to account for. It is stated by Doran, that there are thirty-nine families in Europe out of which crowned heads are chosen; you may remember it as the number of stripes given the Israelites—forty save one; of these, twenty-five are affirmed to be positively scrofulous. Why should they be scrofulous? They feed sumptuously, they are clothed in purple and fine linen, they are magnificently sheltered, and live under as good hygienic rules as are practicable; their children are not badly reared; royal females bring up their children well; they are taught gymnastics, riding, shooting; care is taken to bring them up with a view to their physical development—yet they are scrofulous. We must go far back to the original stock, when they were not in this condition. The house of Hapsburg is famous for its thick lip—and a thick lip is said to be one of the characteristic marks of scrofula. The house of Brunswick, which occupies the throne of Great Britain, is known for many years to have been subject to scrofula. We owe the fashion of wearing high stocks to a Duke of York, who endeavored in this way to hide the glands of his neck and the results of ulceration. There is nothing in the habits of these families which produces scrofula, nor has there been for a generation or two back. Some even go so far as to allow but a single healthy family to exist on a European throne, and this is the superior race in power, the house of Hohenzollern, on the throne of Prussia.

As a general rule the crowned heads, the royal families, are at one end of the scale of humanity, the poor artisans in the manufactories at the other; and thus we have an exemplification of the old proverb that extremes meet. Something must be owing to climate. Almost all the crowned heads of Europe are derived from Germany; it were easy to suppose, then, that there is something in temperament and individual constitution, for the individual constitutions of that race present certain peculiarities; they are fair-haired, with blonde complexion and blue eyes; and thus we have imbibed the idea almost universally acknowledged, passing from book to book, with very little doubt or hesitation, expressed with great stress, meeting with no denial, that scrofula especially attaches itself to the light-haired, the blue-eyed, the blonde complexion. Certainly the rule is not absolute; a crowd of instances to the contrary present themselves to my recollection. Whether from crossing, or otherwise, Holmes observed in this country, and it has been observed, too, in Europe, that this fair race is decreasing in numbers, and the dark complexion, the black-bearded races, are predominating over the entire world. In the various miscegenations taking place, this seems to be the prominent type, which will prevail ultimately everywhere; the other type dying out, perhaps from weakness originally, and therefore the more readily deteriorated. Hybridism, or crossing, has been supposed to be the cause of many evils; but on the other hand, we are warned that the marrying in and in is productive of great evils. Several writers on both sides of the Atlantic, on this side Prof. Bennis, now of New Orleans, ascribe much of tuberculosis and scrofulosis to the marrying of relatives—physical incest, as it is called. I think the truth can be put in a nutshell. I suggest it to you; there is a great deal of exaggeration on this subject, yet there is much reason for the belief that the intermarriage of relatives is dangerous to the offspring, not on account of their mere consanguinity, but because they are likely to have the same predisposition to scrofula if that predisposition exist in that family. The healthiest and hardiest race in the world, and one of the best intellectually, D'Israeli says *the* best intellectually, are the Jews. Brace says, they are divided into two races, the light clear-complexioned, and the dark race. They have kept these peculiarities separate from the earliest times; they marry in and in, as we know; breed continually together. Jews seldom intermarry with the races among which they live. Gentiles seldom marry with the Jewish race. There are such exceptions and the intermarriage does not seem to be uncongenial; they form a good race, generally mingle well together. Here then, we have an instance of long continued intermarriage, of marriage of relatives, and without any deterioration. With regard to degeneracy in them, scrofulosis and tuberculosis are certainly not necessary results of their intermarriage.

Burton says, it is the same with the Arabs, and the Arabs are likewise divided. The Arabs are Ishmaelites, and they are divisible into two classes, the blue-eyed and the dark-eyed. Abd-el-Kader is blue-eyed and a blonde; yet some of his race are dark, even blacker than the Hindoo. These are closely intermarried—intermarried even among tribes, as we learn. Among the smaller tribes of Bedouins, all marry their own cousins—there are no others to marry—yet physically they are a fine race, athletic, energetic, active. What can you desire in physical health and development more than they possess? Consanguinity is not therefore among them necessarily followed by degeneracy. We are told the same thing of the inhabitants of a certain part of France. The Basques and Bretons marry their cousins and kindred habitually, and there are no degeneracies of any kind, physical or mental, among them.

Therefore we come to the conclusion that it is not an essential result of marriage of consanguinity, that there should be scrofulous or other degeneracy. Why then does it often happen, for there is no doubt that it does often happen, that marriages of consanguinity are followed by physical or mental degeneracy? Because, if there is any predisposition to disease in a family, the female will have it as well as the male; if then, under such circumstances, two cousins of similar scrofulous predisposition marry each other, it is certain the offspring of these cousins will be more scrofulous than their parents; but it is not so by the law of consanguinity. For suppose two persons scrofulously predisposed, of the most distant and diverse race, marry, the result will be just the same without the slightest consanguinity. It is due to the predisposition and not to the blood. It is, for this reason, more apt to be encountered among married relatives; but it is not essential, it is not a law. If two cousins are healthy and see fit to marry, there is as much reason to believe that their children would be healthy, as if they were not connected by cousinship or consanguinity at all. If the temperaments be opposite, it will be as favorable a conjunction as if they were not connected. If we could manage these things as the stock-breeder does with the lower animals, undoubtedly we could improve the human breed to a great degree.

As the scrofulous diathesis discloses itself, we find a universal predisposition to various phenomena, various morbid manifestations of the skin, the eye; the bones themselves becoming soft. Rickets we scarcely know in this country, though frequent in many other parts of the world. Softness of the bones of various kinds, spina bifida, etc., the child being born with the defect. This has led to another suggestion. We cannot readily cure this terrible form of disease in a given individual, but we can prevent it in the offspring by removing the cause. The defect of lime is said to be the cause. Mouries discovered that the milk of women in the city of Paris contained less of earthy salts than the proper proportion. Now in defects of the kind we are speaking of the earthy salts are wanting too, and acting on the suggestion resulting from this investigation he found that by sending the children out of Paris, and by procuring for them the milk of country women, this difficulty was abated; and the result has been, that at the present day very few children in Paris are nursed by their mothers. We learn that this is really so from works of fiction, from poetry, in sadder numbers than are recorded in our medical books, for it has produced a sad state of morals in that city. Stone, of New Orleans, believes that in all scrofulous and tuberculous cases, the phosphate of lime is an excellent remedy. Many others have maintained the same thing. Lime salts are necessary to remedy this defect, and the want of the lime salts in the maternal parent is one of the modes of accounting for the presence of the disease hereditarily.

Have we any mode of treatment for scrofulosis? Are there any means of cure? Any articles of diet that will prevent it?—How shall we treat scrofula? Take any of its manifestations. One of the most interesting is the affection of the cervical glands. You find a child beginning to show a ready swelling of the lymphatic glands anywhere, no matter where; you find children very liable to enlarged tonsils, to irregular irritative diarrhœa, to sore throat, to glandular swellings externally, to swelling of the lymphatic glands everywhere, under the arm in the axilla, along the bend of the arm; you will be able sometimes to trace from a slight blow,

a swelling of the duct along the whole arm up to the axilla, inflamed, uneasy, sore to the touch. All this liability depends on a certain hereditary predisposition. Iodine is proposed for these conditions, and the various modes of administering iodine are now among the favorite remedies. I do not believe it to be so generally and universally applicable as has been supposed. For instance, to a true development of scrofulous degeneracy it does not seem to me to be very applicable. Marasmus I hold to be one of these manifestations. A child thus affected will begin to swell with a sort of general, irregular, knotty hardness of the belly, and at last you will find the mesenteric glands quite enlarged. This goes on to an enormous extent. I have seen in one child an enlargement, a mere tumor, an immense mass of these glands, agglutinated together as large nearly as his head; you frequently find them as large as the fist. It is a common thing to say there is tuberculous deposit in these cases; I have never seen it. Lloyd describes the manner in which the glands of the neck are thus changed; hyperæmia first shows itself; the glands are in a state of determination, a stagnation of blood soon followed by inflammation, then there is exudation, but not of the kind to be described as tubercular; it is a thin curdy fluid which will sometimes form a cavity—like an abscess; but sometimes the inflammation is of ordinary character. I have repeatedly opened these glands in the neck, when I found pus as laudable in appearance as any surgeon would find in a common phlegmon. At other times it does present a curd or whey-like separation of a fluid, thin stripes of pseudoplasm, with a turbid serum.

Iodine seems very readily to affect the external glands. I don't think it relieves the tonsilitis, or the hardness, redness, and induration of the tonsil, which by and by causes necessity for extirpation; nor does it seem to benefit the subject of mesenteric glandular swelling, which is entirely out of the reach of iodine.

Mercurials, which I object to, and dislike to use under all other conditions of scrofula, which I think rather tend to irritate and disturb a scrofulous constitution otherwise affected, seem to be essentially necessary; and yet you must avoid with great care the local irritation and inflammation, the buccal and parotid inflammation likely to be produced. Mercury must be used in small quantities. Without it I do not think you will relieve a child from this sort of irritation; marasmus, as it has been called, a wasting away, a very rapid atrophy of the whole body, shows itself, and the child emaciates in proportion to the enlargement of the glands, from the injury done in the general disturbance of the assimilative powers of the constitution, which is coincident with the mesenteric swelling. I have opened these swellings after death and found them in the state which Lloyd describes as existing in the glands of the neck. I have never seen the yellow tubercle in any of these glands; I have seen the white curdy matter which may be, I don't think that it is, identical with the grey matter of tubercle. These two subjects, scrofula and tubercle, run together inextricably at certain points, but they are not identically the same conditions. I would rather let alone even inordinately swollen cervical glands in a scrofulous subject. I do believe there is something favorable, on the whole, in their appearance, whether it be metastatical, as Parrish believed, by saving other parts; or whether it shows a not quite so great degeneracy of constitution, attacking external glands instead of internal glands, I am not prepared to say. It is a better condition of things than internal manifestations; frequently they remain indolent at a certain point for a long time. Let them alone; follow the practice of one of our late physicians who advises you "if it lets you alone, let it alone." They frequently disappear of themselves, subside readily; and thus is accounted for, the value of the "royal touch," which is one of the earliest superstitions we know of. If we trace its history closely we find that it was employed among barbarous nations. Vespasian was supposed to have this power of gracious touch, by which he also relieved blindness and paralysis, etc. "*Stitim conversa ad usum manus ac cæco dies relaxit*," says Tacitus: "the hand recovered its power and the day returned to the blind." Laird tells us that Knig Olaf, one of the earliest Norwegian kings, had this singular power. He took a piece of bread, rolled it, made the form of the cross, put it in the mouth of the patient; he then stroked the neck and the glands disappeared, and thus he showed the royal power he derived from heaven. We know that the kings of England employed the royal touch, and the queen down as late as the time of Dr. Johnson. We know of other persons who have enjoyed this power. Valentine Greatrakes has left a name in history on account of the number of cases that occurred under his hands.

Scrofulous persons, therefore, grow up very often in good health, get rid of the scrofulous affection of the eye, of the skin, and of the glands.

Internal scrofula is not so readily got rid of; nor are the scrofulous affections of the bones. Toynbee says that the general deafness met with in cities, especially where ochlesis prevails, is also a scrofulous affection. Iodine is used in all these, and in all the external manifestations it seems to be singularly applicable. Whether goître is one of these or not is much disputed. I think it is, for it is much under the influence of iodine. How shall the iodine be administered? There are many modes. I prefer Lugol's solution, very weak; a grain to the quart of water, and administered in doses of a wine-glass full two or three times a day. Thus you avoid the irritative absorption of healthy glandular structure which sometimes follows the administration of iodine. The deutiodide of mercury and potash is one of the best preparations and very effective. All the salts of potash are serviceable, upon a particular view which Garrod gives us. He says all the alkaline salts tend to promote the natural metamorphosis of tissue going on in the system; that under the influence of the alkalies there is a more ready metamorphosis of the less vital tissues, less vital deposits, less vital plasma, and of course the deposition forming the glandular and other swellings of scrofula. I have no doubt he is right. A combination of salts, such as we have in sea-water, I have found excellent. Recent sea-water, every day, in small quantities, will improve the health. All the natural impregnations of mineral waters which go to assist the metamorphosis of tissue are beneficial, and upon that general principle. I know no other to guide us; there is no specific unless iodine is a specific; but it acts, I think, on this general principle of Garrod.

With regard to the diet much may be done. Bennet suggested long since that such depositions are chiefly albuminous; many books call them fibrinous; but there is very little difference between the two in our view. In either case it will be of great consequence to avoid albuminous food. Bruce also says that they contain too much caseine among the proteine compounds. Bencke confines his patients to a diet of whey; subtracting from the milk the whole of the albumen, leaving the sugar and other ingredients, getting out the curd, he gives the whey. It is said that the cures under his hands have been marvellous. Very little bread is allowed, great quantities of whey being drunk. Even the manifestation of tubercle is said to disappear under this regimen.

Reports of Hospitals.

JEFFERSON MEDICAL COLLEGE

OF PHILADELPHIA.

SURGICAL CLINICS OF PROFESSOR GROSS.

WEDNESDAY, Dec. 19, 1866.

Enlarged Prostate.—A. G. M——e, æt. 61, presents himself for examination. He has had vesical trouble for six years; passes urine several times during the night, and two or three times in the day-time; this is not accompanied by a scalding or burning sensation. Introducing the sound into the bladder, it passes very high up, and over a very rough surface; the finger in the rectum discovers an enlarged prostate, which condition was sufficiently diagnosed by the fasciculated condition of the bladder. The bladder is much thickened. There is a partial paralysis of this viscus most probably, and its interior is very much enlarged, admitting the exploring instrument even to its very handle. The urine should be examined as to its quantity and quality; as to whether it is unnaturally acid or alkaline, or contains an unusual amount of mucus, or contains any phosphates, urates, or any other deposit; whether it contains any pus, etc. A great deal of information is to be obtained in this way before we can reach an accurate diagnosis; but the cause of the entire difficulty is enlargement of the prostate gland, leading to mechanical obstruction to the egress of the urine, and to hypertrophy of the walls of the bladder.

Such a disease is incurable. All that can be done is to palliate the symptoms and relieve the suffering of the patient to the extent to which that can be done. We cannot remove this hypertrophy. Hydrochlorate of ammonia, iodide of potassium, bromide of potassium, and similar articles, have been employed internally with this view. Of these remedies the hydrochlorate of ammonia is preferable. Sometimes suppositories may be introduced with advantage, but this is about all that can be done towards relief. The application of leeches to the rectum and vicinity, the application locally of iodine, etc., all prove inefficient; and whatever we may try, we find at last that nothing can be done to diminish permanently the size of the organ; and as long as the obstacle to the egress of the urine remains, just so long must the difficulty in the bladder remain.

In the present case (the patient has never had retention of urine) there is paralysis; the bladder is not able to contract well upon its contents. He will be directed to take one drachm of Tr. secale cornutum, with twenty drops of the Tr. ferri chloridi four times daily, adding ten drops of the Tr. cantharidis—another excellent remedy in these cases of incontinence of urine where there is paralysis of the bladder. Secale promotes muscular contraction of the muscular fibres of the urinary bladder; cantharides acts specifically on the urinary passages; and the tincture of the chloride of iron also acts on these organs, and is an excellent tonic besides; and therefore, the combination is a proper one under the circumstances.

The bowels are to be kept in a soluble condition, with an efficient purgative occasionally. The diet is to be simple and nutritious.

Another Case of Enlarged Prostate.—This is in a deaf and dumb gentleman, who presents himself for relief from incontinence of urine. He is wearing an ordinary urinal, in which the urine is received as it flows, and from which it is emptied at convenient periods by turning a stop.

There is another contrivance much superior to the ordinary urinal, which was originally worn by Mr. Head, a man with a congenital extrophy of the bladder. In these cases of extrophy, the anterior wall of the bladder is deficient, and the posterior wall protrudes so that the openings of the ureters can be distinguished. After wearing a great variety of instruments for the purpose of collecting the urine, he finally had an apparatus constructed which runs along the inner side of the thigh, and the reservoir is long and slender, and is attached above to the pubes, while the tender tumor is covered by a protector, and the urine, as fast as it passes off from the ureters, is received in the reservoir, and conveyed along the instrument, where it is retained, and evacuated by means of a screw, several times a day.

This patient was examined with the sound without finding a stone, and as in the previous case, giving evidence of an enlarged prostate gland. There is precisely the same condition of the bladder as in the other case; it has become fasciculated from irritability. The probability in the present instance is that the middle lobe of the prostate forms some mechanical obstruction to the evacuation of the fluid, leading to paralysis of the bladder, and incontinence as a result. Very frequently the enlargement exists both on the part of the lateral lobes, and of the middle lobe; at other times it exists in one or in both lateral lobes; and occasionally, exclusively, or nearly so, on the part of the middle lobe. When the middle lobe is enlarged, then a projection resembling much the uvula is formed, which serves as a mechanical obstruction to the evacuation of the urine, and there is no particular remedy unless we cut it off, or seize hold of it with a loop of wire, and get rid of it in that manner. A good mode would be to get in to the bladder in a manner similar to the lateral or median operation of lithotomy, and then to snip off this middle lobe; there might be a little bleeding, but not to a serious extent, and thus we might dispose of this body which we cannot get rid of by any medication. This operation would be safer than to seize it with the écraseur.

When there is enlargement of the lateral lobes, one or both, equally or unequally, then the passage is very much narrowed, and we can literally do nothing—because we have no remedy to relieve hypertrophy of that organ.

In the present instance, various remedies have been employed, none very persistently, and the consequence has been that the patient has not experienced much relief. The excoriated condition of the penis in this case would lead to the inference that the urine is acid, and the prescription will consist of tr. ergot ℥j. three times daily with soda bicarb. grs. xv. to each dose; with the introduction every night at bed-time of a suppository containing one-half gr. of morphine rubbed up with ℥j cocoa-butter. This treatment will be continued for ten or twelve days, in the hope of affording considerable relief.

Occlusion of the Urethral Orifice.—John M——y, æt. 11, has had great difficulty in passing water for about a year. The orifice of his urethra is barely distinguishable. The prepuce has become firmly adherent to the head of the penis, from inflammation produced by irritation of the prepuce, due to a want of cleanliness. When the sebaceous matter in this situation is allowed to accumulate it is very apt to excite inflammation, and if the patient is too young to know the importance of ablutions, it may lead to the present state of things.

In operating for the removal of this difficulty, enlarging the orifice and separating the prepuce from the glans, a strong membrane, apparently fibrous, was found

stretched over the meatus urinarius, and the adhesions were very firm. An affection of this kind will lead to disease of the bladder and ureters; it may lead to calculus, from collection of the salts of the urine as a result of the difficulty in micturition. Hypertrophy of the bladder is a common consequence of this condition.

Progress of Medical Science.

Diphtheria.—Dr. E. S. Gaillard, Richmond, Va., in a Prize Essay on Diphtheria, comes to the following conclusions:—"That diphtheria is a zymotic disease; peculiar, separate, and specific. That its pathology proves it to be a distinct disease. That its anatomical and physiological relations appertain to no other disease. That it is both epidemic and sporadic, in its prevalence. That its etiology is obscure and in no respect understood. That its symptoms and course render its diagnosis and differential diagnosis simple. That it is often contagious; but not so always. That its duration, in the acute stage, is from three days to three weeks, and when its peculiar sequelæ ensue, that the disease may persist for many months. That hygienic influences seem not to affect the cause of the disease; but that they do affect its course and result. That its relation to age is marked and direct; that children are its most frequent subjects and its most frequent victims. That its complications are numerous and most of them dangerous. That there is no direct relation between the throat lesions and the result. That it is peculiarly apt to recur; and that convalescence from its attacks is slow, tedious, treacherous, relapsing, and interrupted. That there seem to be diseases coincidently occurring in the lower animals, during its prevalence. That its sequelæ are peculiar and such as are not seen after any other disease. That its mortality, when uncomplicated, is not serious; but that its frequent complications render the mortality severe. That the chief cause of death is laryngeal implication, and next to this asthenia. That the prognosis can seldom be satisfactorily made. That, in no disease, does treatment more generally influence the result. That the autopsies prove (what is indicated by the pathology, the anatomical peculiarities, the symptoms, and the sequelæ) that diphtheria is a zymotic, distinct, and specific disease. After a careful analysis and patient tillage of this field; after freely consulting all familiar with its cultivation, we now offer to our fellow-laborers the results of the harvest: 'Corn from the sheaves of science,' with the stubble, produced to sustain it."

Menstruation in the Male.—Dr. V. O. King reports (*Southern Journal Medical Science*) a very curious case of simulated menstruation in a male. The subject was a fellow student at the University of Louisiana whose intimate acquaintance he first made during the month of December, 1855. He then learned that the gentleman had been the victim of this vicarious function for a period of three years, eliminating an apparent catamenial secretion, with the same regularity and attended with the same indications by which it is characterized in the human female. The fluid exuded flowed from the sebaceous glands of the deep fossa behind the corona glandis, and was of a sanguineous appearance, homogeneous, and thick. The quantity of this exudation varied from one to two ounces during each hæmorrhagic period, and the duration of the periods from three to six days. The subject was then twenty-two years of age, of a lymphatic temperament, and had never been contaminated with venereal disease. Though not prone to the indulgence of lustful passions he was not innocent of having sometimes yielded to their promptings, which were especially potent immediately preceding his periodical purifications.

Incontinence of Urine Successfully Treated with Extract of Belladonna.—A healthy looking country girl, fourteen years old, was brought by her mother to the *Metropolitan Free Hospital* on the 11th of January last. She had suffered from nocturnal incontinence of urine for the last two years. Not a night passed without her wetting the bed, and to such an extent that she had been compelled to lie upon straw covered with a sheet in order to change her bedding daily. She had been taken out of bed at night, scolded, and ridiculed, without any effect in making her abandon the habit. Dr. Drysdale ordered her a quarter of a grain of extract of belladonna as a pill, to be taken at bedtime every night. On the 15th of January her mother came to say that she had not wetted her bed since taking the medicine. Up to the 18th of January there was no return of incontinence of urine. Dr. Drysdale remarked that he had in many cases seen similar results from the use of belladonna in this disease, and supposed that the drug acted by paralysing the detrusor urinæ muscle.—*Lancet.*

Detection of Strychnine.—It frequently occurs that when strychnine is mixed with organic matters—as usually happens in medico-legal cases—though the ordinary tests may be applied without much difficulty, it is by no means easy to detect the crystalline form of the alkaloid. A suggestion lately made in the *Chemical News*, by Mr. Blunt, appears of some value. He says that the granular masses of the alkaloid which are seen in organic mixtures containing strychnine may be converted into exquisite stars of crystals by the addition of a drop of sulphuric acid, if consisting of one drop of strong acid in five of water.—*Lancet.*

Trichinosis.—A committee appointed by the Medical Society of Vienna, and composed of Professors Klob, Muller, and Wedl, has just published a long report on trichinosis, in which the startling fact is asserted that the real source of infection lies entirely in the rat, in which the malady is spontaneously developed, and which communicates it to the pig. In Moravia, eighteen out of forty-nine rats examined were trichinized, a proportion of nearly thirty-seven per cent. In Lower Austria the proportion was not more than four per cent., and in the environs of Vienna about ten per cent. The report confirms the fact that trichinosis may be transmitted by food, from the rat to the rabbit, from the rabbit to the fox and hedgehog, from the rat to the pig, and from the pig to the rat. Even the calf may be infected by being fed with the flesh of trichinized rabbit. What is worse still, the larvæ of flies feeding on infected meat will transmit trichinosis to rabbits, provided the larvæ come fresh from the infected substance; for if a certain time be allowed to pass, the trichinæ soon die in the digestive tube of the larvæ. It is important to notice that the report distinctly confirms the innocuousness of trichinized meat when thoroughly salted, smoked, or boiled, the latter process being by far the most efficacious. Meat roasted for three-quarters of an hour is safe food; boiling requires a whole hour. And yet the report mentions cases of infection recently observed in Austria, so that means should be taken there to protect the public from this disastrous malady. The first measure proposed is the extermination of all rats and mice, but not without previously examining them, in order to ascertain the existence of trichinosis among them. If this examination should lead to affirmative results, then particular care should be taken in the locality to

keep pigs away from all sewers, heaps of manure, and other such places frequented by rats. The flesh of the pig should be examined either after death, or even during life, by means of incisions. The infected pig should be separated from the others, marked, and its sale prevented. Special slaughter-houses should be organized for pigs, and the flesh examined by veterinary practitioners; and the public themselves are warned never to eat raw pork under any form, but strictly to consume it only well salted or smoked, boiled or roasted.—*Exchange.*

Eye-washes containing acetate of lead have been found to produce a precipitate of chloride of lead upon the cornea which renders it dim, and forms erosions upon it by destroying the epithelium. The ulcers which are formed are very obstinate, and a condition of things is induced far worse than the original trouble for which the lotion was prescribed.

Excision and Regeneration of the Entire Clavicle.—J. W. Irvine, L.R.C.S., Edin. (*Lancet*), reports a case of excision and regeneration of the entire clavicle of a lad aged sixteen. The necrosis of the clavicle which necessitated the operation, was caused by severe osteitis following rheumatism. On admission to the West Derby Union Hospital, June 18, the patient was much exhausted; there was a constant purulent discharge from a wound which left an inch and a half of the central portion of the right clavicle bare and dead. He continued to lose flesh until the 2d of July, when abscesses began to show themselves near the sternum and scapula. This latter circumstance decided the surgeon to operate.

Chloroform having been administered, an incision was made over the entire length of the bone, and then, as far as possible, the periosteum was dissected from its superficial surface. Then the sterno-clavical end was disarticulated, and a spatula so placed as to elevate the bone, and allow of an easy separation of the periosteum. The operator found it necessary to dissect with extreme care owing to the painful perceptible pulsation of the subclavian artery, but with perseverance he managed to remove the clavicle comparatively free from its periosteal covering. During the removal, hæmorrhage occurred from seven sources. Three vessels were controlled by torsion, and he found it necessary to apply four ligatures. The wound was brought together by eight wire sutures; the arm was confined at right angles across the chest by means of bandages, and cold water dressings were applied. No secondary hæmorrhage occurred, and in a week the scapular end of the wound had healed by the first intention, and the arterial ligatures had been removed. The abscesses which had threatened to point near the sternum and scapula had discharged themselves at the line of incision. The sternal end of the wound, which was healing by the granulating process, had a tendency to gape, but filled up very satisfactorily; the patient being confined to his right side, and having his head thoroughly elevated. On September 1, two months after operation, the entire wound had cicatrised, and the patient had gained in weight. He had been able to sit up, and use his arm in playing dominoes, for ten days past.

On September 20 he expressed himself as quite able to follow his employment, and as it was evident that the clavicle was being regenerated he was discharged with the caution to use the arm of that side tenderly. The operator, in commenting upon the case, remarks, that an examination of the clavicle after removal convinced him, and every other surgeon who saw it, that any operation short of entire extirpation would have proved unavailing. The scapular end of the diseased bone, especially its under surface, was found to be most affected, but the sternal end was considerably disorganized. The articular surface of the sternum was healthy. On the 31st of December, six months after operation, he had an opportunity of seeing the patient for the first time after his discharge, and found that he had meanwhile been actively employed at his own business, and had for some weeks been able to use his right arm as perfectly as ever. Occupying the place of the resected clavicle is a new bone, of rather beyond the normal length, and considerably wider, but more flat and thinner, than the original one. This regenerated clavicle played its part with perfection, allowing the boy to use his arm as efficiently as though no disturbance of the parts had taken place. It was interesting to him to notice the accuracy with which the limits of attachment of the clavicular muscles could be clearly defined when muscular efforts are made.

Repeated Resection of the Knee-Joint.—Several cases have occurred in which delay in healing, and the evident occurrence of necrosis after resection, has rendered a second operation necessary. At *King's College Hospital*, under such circumstances, it is thought better to repeat the resection rather than to amputate the thigh. Sir William Fergusson has had three or four such cases, which have done well; and Mr. H. Smith had one in which the proceeding answered perfectly. On Saturday last Mr. Smith again adopted the plan in the case of a lad whose knee-joint he had excised in July last. The boy went on well at first, then fell back, and was sent into the country for a few months—not to much purpose, however, for sinuses about the wound persisted, and showed the presence of dead bone, and the boy's health was suffering from the prolonged irritation. On opening up the wound, firm anchylosis was found to a limited extent between the femur and tibia. Lying behind the former bone was a ragged sequestrum, an inch or two long, representing the intercondyloid space of the femur—that portion of bone which is so often exposed to necrosis. There was an abscess in the head of the tibia. Mr. Smith removed a thin section of this latter bone and a portion of femur, and brought the bones into apposi ion again just as in ordinary resection. When the sequestrum came to be examined, an old arterial ligature was found lying about it. This must have been accidentally dropped into the wound in July last, at the time of operation, and there it had since rested. Was it the presence of this piece of string which excited inflammation leading to the death of the shell of bone described?—*Lancet.*

Narceine.—The employment of narceine is becoming very fashionable in France, morphia being in the meantime thrown virtually aside. It is said to possess the property of producing a tranquil sleep, at the same time none of the unpleasant effects belonging to other narcotics are felt on waking. It has another valuable property of not interfering with the regular and normal action of the bowels.

For Relaxed and Elongated Uvula.—A correspondent of the *Lancet* calls attention to the beneficial effects of the local application of a strong solution of sesqui-chloride of iron to the throat in cases of relaxation of the uvula. It should be applied twice daily with a camel's-hair brush.

A Cause for the Inefficiency of the Davy Lamp.—The evidence given in regard to one of the recent colliery explosions in England shows that the men were in the habit of smoking in the pit, and that they carried duplicate keys, by which they opened the safety-lamps.

THE MEDICAL RECORD.

THE CONVENTION OF MEDICAL TEACHERS.

A CONVENTION of Medical Teachers, in accordance with the recommendation of the American Medical Association, is to be held in Cincinnati, on the 3d of May next. The object of the meeting is a thorough revision of the present system of medical college instruction. The committee appointed to carry out the spirit of the resolution have issued the call, and have propounded certain questions which they desire the several delegates to consider, and be prepared to act upon.

The first subject to which they are asked to give attention, is the establishment of a uniform and just rate of lecture fees. It is well known that many of the eastern colleges have increased their rates during the past season, while others have chosen to adhere to the old price. The experiment has received a fair trial, and the results must prove the wisdom or folly of the change. We are not among those who are disposed to cheapen medical science, and are in favor of teachers being decently, in fact well paid; but at the same time the students should have a decent show. If those attending lectures have been satisfied, as may be shown by their coming out in numbers proportionate to former years, there is no argument against the adherence to the present rates; but if the reverse can be demonstrated to be the case, some compromise must be settled upon. As far as we can learn, however, those schools which have raised the tariff are satisfied with their course, and are willing to urge every reason in favor of its universal adoption; maintaining that any lack of attendance can be explained by other causes than those which refer to a mere advance of thirty or forty dollars on former years. It is probable that the arguments of these gentlemen will have merit enough to convince other members of the convention of the practicability of their plan. If they succeed, a settlement upon a uniform rate of charges will not be difficult. But after all, the matter is not of much importance, only as it bears upon another question, which is advertised to be presented, viz. the increase of the lecture term, and of the number of professorships. The adoption of such a measure would certainly involve an increase of expenditure, and would necessitate a proportionate increase in lecture fees. This must be the main ground upon which its justice is to be founded. If the teachers promise to extend the lecture season and increase the number of professorships, it is but right that their patrons should stand ready to help them pecuniarily; but if no increased advantages are offered, they should show some very good reasons why they cannot adhere to the old prices.

The propriety of increasing the lecture term has been already discussed in our columns. We have taken occasion to raise our voice against the miserable cramming system involved in the giving of six lectures a day, and to urge the practicability of having but three or four. There is no earthly reason why the course should not be nine months instead of five. The professor may do the same amount of work in that time that he now performs in a shorter one, the only difference being, that by allowing time for the student to digest what he has heard, he can do proportionately more good. But we cannot dilate upon this point without the risk of repeating views already familiar to our readers.

If the lecture term be extended, the increase in the professorial corps can naturally follow. In fact the agreement to the first proposition would be absolutely necessary, unless the poor victims of over-lecturing are to be crowded still more. The increase in the number of professors would hardly involve the necessity for more than one to each branch, unless a more systematic course of instruction than is now followed out, is agreed upon. This would seem to be the intention of the committee, in an invitation to a consideration of the third question, in which they urge the "adoption of measures for securing more thorough attention on the part of students to the more elementary branches of medical science, and a more progressive order of medical studies." The only way, in our opinion, this can be done, is by a regular division of the class into yearly grades, the adoption of which measure we have, in a preceding number, taken pains to urge upon all the medical colleges. The reasons for our convictions have been, we think, fairly presented, as affording the best means for properly regulating the studies of the different branches. If the medical class is divided into first, second, and even third course students, it may then be requisite to have two, or even three professors; but in that case each teacher should have his own pupils, so that any of his peculiar views may not be combated by his confrère.

The proper discussion of the question in reference to the establishment of a more progressive order of studies, covers considerable ground. In the first place, the propriety of establishing recitations is one which should be considered as having a very important bearing, and in the second place, the necessity of having examinations for the different grades. Recitations should be regularly carried on, and no student should be allowed to pass into a higher grade until he has given satisfactory evidence of his fitness by a sufficiently rigid test.

The proposition to exact attendance upon three annual courses instead of two, is one to which the attention of the convention should be seriously directed. We cannot see what objection there can be to its unanimous adoption; the majority of the students are already in the habit of attending three courses instead of the two which they are compelled to. The only difference it would make to them by extra attendance being compulsory instead of a matter of choice, would be the increased expense which such a regulation might involve. But this can be reduced to the minimum by the colleges, especially if most of the course be devoted, as proposed, to clinical instruction. It could, in fact, be so arranged that an extra pecuniary outlay would be uncalled for.

Lastly comes the subject of preliminary education. We are glad to see that the committee has the hardihood to propose the question and rank it in equal importance with the preceding ones. If they had left this out, a general discussion upon college education would be without much practical result. The committee do not, we imagine, intend to do more than make a beginning in this matter. The regulations cannot, to start with, be very stringent. The young men who are candidates for the study of medicine should not be startled with the announcement that unless they are versed in the dead languages, and proficients in those other branches taught in our literary institutions, they cannot enter a medical college. It would be much better for the science if some such regulations could be adopted, but in the present state of affairs we must look at such a culmination of our hopes as afar off. But how is a beginning to be made? Simply by insisting at first upon a reasonably low standard; by the establishment of a code of requirements which shall be rigidly and impartially adhered to. By so doing, those proposing to enter upon the study of our art can be made to understand that the portals of our colleges are not open to every blockhead who may have money enough to purchase his tickets. After a while we can gradually increase the stringency of our demands and eventually equal those of the colleges of Europe. Let us be satisfied at first with a little, but let us have that little at all hazards.

There will probably be a multiplicity of topics growing out of the subjects which are to be presented by the committee; but with these we have nothing at present to do. We only desire, in the cursory review of the subjects proposed by the committee, to offer a few suggestions upon the pursuance of a course which will meet with the support of the majority of the profession. There can hardly be a doubt that the convention will be a large one, and that every medical school in the country will feel enough interest in the objects of the meeting to be represented by delegates. If we are right in our conjectures, and the meeting be, as we hope it will, a harmonious one, the members will have the opportunity of settling many points which have heretofore remained unsettled from the lack of a properly recognised power to take them in hand.

Not only do we hope this meeting will be well attended, but that out of it may grow a regular organization of medical teachers, which shall be an auxiliary of the American Medical Association, and shall meet as often as occasion may require to discuss all matters relating to medical education. The establishment of such a society would in fact be the only means we at present can have of raising the standard of medical learning. We may exact this and that at our medical organization, concerning what college shall and shall not do; but what does it avail us if the professors refuse to comply with our demands? If, however, we have a recognised association of teachers who understand what is to be done, and who agree to act in accordance with their convictions, we shall have something tangible upon which to rest our hopes of radical and practical reform.

THE Society for the Prevention of Cruelty to Animals seems determined to stultify itself, not only in the eyes of medical men but of the public at large. No one seems proof against the misdirected zeal of its representative. Not long ago we had occasion to allude to an attack made upon a distinguished professor of physiology, of our city, for exercising unwonted cruelty upon animals which he experimented upon. The sensational breeze which this charge against that gentleman made in the public prints was happily of short duration, in consequence of the very sensible and able defence that was made. But the indefatigable chairman of the association has seemingly not been contented with this rebuke, and we find him drawing his quill against another party, upon an equally frivolous and unfounded pretence. It seems that a certain party complained, in the sentimental style peculiar to abnormal tender-heartedness, that the well known manager of a museum was in the habit of feeding his snakes with live rabbits, which were thrust into the reptiles' cage. This seems to have been enough to arouse the champion of animal rights, and a correspondence was at once commenced. The showman was not backward in his reply, and proved, as any one could easily do who was acquainted with natural history, that it was necessary to feed these reptiles in the way he did. Not wishing to rely upon his own opinion he solicited that of the distinguished savant, Agassiz, who gives the following amusing and suggestive reply: "I do not know of any way to induce snakes to eat their food otherwise than in their natural manner; that is, alive. Your museum is intended to show to the public the animals as nearly as possible in their natural state. The society of which you speak is, I understand, for the prevention of *unnecessary* cruelty to animals It is a most praiseworthy object, but I do not think the most active member of the society would object to eating lobster salad because the lobster was boiled alive, or refuse roasted oysters because they

were cooked alive, or raw oysters because they must be swallowed alive." If similar senseless exhibitions on the part of the attacking party are made, the public will eventually look upon the society in the same way as the profession have been led to do, and much distrust will be engendered as to any of the real benefits which might grow out of a proper direction to its efforts.

We are glad to notice that the enormity of the crime of abortion is beginning to attract the attention of those laymen whose opinions upon moral and religious questions command the respect of the community. The *North-Western Christian Advocate*, of Chicago, in a well written, elaborate, and truthful article, fearlessly commences the discussion of this subject. This is the first instance in our knowledge in which a religious paper has dared to give the theme a fair and full notice, and it is to be hoped that the community to whom the remarks are addressed, may receive them in the same spirit in which they are given. The example of this periodical should be followed by others, as by the proper presentation of the ample facts in the case it will undoubtedly be productive of great good.

Reviews.

The Indigestions; or Diseases of the Digestive Organs functionally treated. By Thomas King Chambers, M.D., Honorary Physician to H.R.H. the Prince of Wales; Consulting Physician and Lecturer on the Practice of Medicine at St. Mary's Hospital; Consulting Physician to the Lock Hospital; Author of "Lectures, chiefly Clinical," etc. London: John Churchill & Sons, New Burlington street. 1867. 8vo., pp. 290.

The work before us, coming as it does from the pen of one of the most accomplished authors of Great Britain, cannot fail to be received with favor on this side of the Atlantic. Any one who has read Dr. Chambers's "Renewal of Life," will be prepared to learn that his remarks on indigestions are thoroughly practical, and full of most valuable suggestions. We have presented to us, first, an introduction, in which the importance of attention to the various phenomena connected with defective digestion is urged; and then follows the regular discussion of the subjects under the following heads: 1. Indigestion of various foods; 2. Habits of social life leading to indigestion; 3. Abdominal pains; 4. Vomiting; 5. Flatulence; 6. Diarrhœa; 7. Constipation and costiveness; 8. Nervous diseases, connected with indigestion; and lastly, an analysis of the whole work. The work is made up principally of a detail of well selected and typical cases, to each one of which are added comments purely clinical in character. The cases cover every conceivable grade of functional indigestion, from the slightest inconvenience after meals to that condition which actually ends the life of the patient. Every useful detail is faithfully figured, in order to carry out the evident design of the writer in making the work as complete and as thorough as possible. No practitioner can peruse it without benefit, nay, without comfort, for he cannot fail to find some of his most puzzling cases of indigestion explained in a clear, practical, and masterly manner. The different plans of treatment are rational, simple, and effective, and the reader is all the time made conscious that they are founded upon clinical experience alone. Associate with this the rare faculty which Dr. Chambers has of infusing an enthusiasm in his subject, and we have in this little work all the elements which make it a model of its sort. We have perused it carefully; have studied every page; our interest in the subject has been intensified as we proceeded, and we are enabled to lay it down with unqualified praise. It is just such a work as every practitioner should have, if he wishes to treat intelligently the majority of the patients who seek his advice. If the book does not prove a great success, and pass through several editions, it will be because the profession do not appreciate fine writing, sound philosophy, and sterling common sense. The work is got up in the usual elegant style of the London House from which it emanates.

An American reprint of this work has been issued by H. C. Lea, of Philadelphia.

The Renewal of Life. Lectures, chiefly Clinical. By Thomas King Chambers, M.D., Honorary Physician to H. R. H. the Prince of Wales; Consulting Physician and Lecturer on the Practice of Medicine, at St. Mary's Hospital; Consulting Physician to the Lock Hospital. Second American, from fourth London edition. Philadelphia: Lindsay & Blakiston. 1866. 8vo., pp. 640.

The title of this work is suggestive of its contents. The author starts with the assumption that disease is the result of defective vital action, and that the business of the physician in treating it is to renew that action. The first chapter, which is a condensation of two introductory lectures delivered at St. Mary's Hospital, on the Relations of Death and Life, lays an excellent foundation for the treatment of the different diseases touched upon in the rest of the work. The author likens the human body to a stately mansion, the different parts of which are constantly undergoing a decay, with greater or less rapidity. In order to keep this beautiful edifice in repair, the wasted materials must be regularly and persistently supplied. This power is known as health; a want of it, disease; and a total cessation of it, death. Life, then, rests upon the power to renew the materials of the body.

In speaking of disease and the importance of associating it in the mind of the physician with defective vital action, he says: "He must look at his pharmacopœia with this thought constantly present before him, with an eye to the ultimate benefit of the patient to a goal beyond that of the immediate effects. He should make his chief thought how each of the re-agents employed will finally touch life; whether they are calculated to add to or diminish the vital functions, to add to or diminish the vitalized substance of which his patient is made; whether by temporarily diminishing the functions or substance he may not remove an impediment to their balanced actions, so as to lead to a final increase, or whether this artificial diminution of functions or substance may not become more permanent, and inflict permanent injury on his patient. The final goal of life-renewal must be consciously or unconsciously in the heart of the physician or in the heart of his guides, otherwise I am sure that he contributes more to the ill health than to the good health of mankind."

This belief of the author is the result of logical deductions from an extensive clinical experience, as will be seen by a careful perusal of the different diseases which are treated of. The remarks upon his cases are so practical, his associations of cause and effect so minute, his plans of treatment so simple, the descriptions so graphic, and style so attractive, that the reader is only made to regret that the range of subjects is not wider, and that the work is not a complete treatise on the

practice of medicine. We cannot too strongly advise every medical man who wishes to acquaint himself more thoroughly with that system of therapeutics founded on the soundest philosophy, to possess the book' to study it carefully, and follow its precepts faithfully. We know of no production which will have a greater tendency to place rational medicine upon that elevated position which it is so justly entitled to.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, JAN. 23, 1867.

DR. H. B. SANDS, PRESIDENT, in the chair.

CARIES AT THE SACRO-ILIAC JUNCTION.

DR. F. H. HAMILTON presented a specimen of caries at the Sacro-Iliac Junction, with the following account of the case, furnished by his house-surgeon, Dr. D. M. Cory.

Catharine Bradford, æt. thirty-four, a native of Ireland, was admitted to Bellevue Hospital, November 26, 1866. She had enjoyed uninterrupted health up to the commencement of the illness from which she died. As far as could be learned she inherited no disease; nor could she recollect of ever having sustained a severe injury of any kind.

In June last she began to experience pain across the loins, especially when stooping, accompanied with lameness in walking. The pain was increased by efforts to turn in bed, or by lying upon the affected side. These symptoms became aggravated, and she at length noticed a swelling in the right lumbar region, which gradually increased in size to the date of her admission. When examined at this time it was large and fluctuating, and very near the surface. There were no abnormal projections along the course of the spine, nor was there tenderness, except over the last lumbar vertebra and the right sacro-iliac junction. She walked with very little difficulty; the little pain which it occasioned being referred to the sacrum; when she stood she leaned upon the sound limb, and kept the knee of the affected side slightly bent and abducted. A small opening was immediately made into the abscess, and its contents (dark and unhealthy pus) evacuated. By the probe a sinus, pursuing a very tortuous course, was discovered, leading apparently towards the vertebral column, but its precise origin could not be reached. She felt relieved after the abscess was opened, and in a few days was allowed to get up and walk about the ward. In a short time the discharge began to increase, and symptoms of consecutive fever became apparent. The pain, from which she had been relieved for a short time, returned, particularly in the course of the sciatic nerve and over the sacro-iliac junction. She could not lie upon the right side, but was quite comfortable upon her back, with her limbs in a straight position. An attempt was made carefully to dilate the sinus, by means of a tent made from slippery-elm bark, but owing to the irritation which it produced it was discontinued. On the second of January she had a chill, followed by a cold sweat; her stomach became very irritable. The discharge from the sinus diminished; chills, succeeded by cold sweats, occurred daily; and the general symptoms of systemic infection became fully established. In a few days her right leg became œdematous, exquisitely tender, and at certain points emphysematous. Effusion occurred into the knee-joint, and the integument around this joint had a dusky hue, which soon changed into a marked gangrenous appearance. The patient now became delirious, and in that condition died, January 11, 1867.

SECTIO CADAVERIS, EIGHTEEN HOURS AFTER DEATH.

Rigor mortis well marked; right leg swollen to double its size, and gangrenous.

Brain not examined; heart and lungs healthy. Abdomen.—The liver was fatty, and the seat of recent peri-hepatitis. This lesion was present also in the spleen. The kidneys were fatty, weighing nine ounces. The sinus, which had opened in the right lumbar region, was traced backwards, and was found to pass through the quadratus lumborum just above the crest of the ilium, and to lead to a large abscess posterior to the lumbar vertebra. A pouch communicating with this abscess had dissected underneath the fascia of the gluteus maximus muscle, and was connected to the latter by a sinus which passed over the crest of the ilium. In front of the vertebræ there was an abscess behind the psoas muscle, and within its sheath, which communicated directly with the sacro-iliac junction; the abscess extending downwards along the psoas muscle to its insertion. There was slight superficial roughness of the right transverse process of the fourth lumbar vertebra, at which point free communication was established between the lumbar and psoas abscesses. The anterior portions of the bodies of the last two lumbar and two upper sacral vertebræ were roughened, and the periosteum and anterior ligament were separated from them by a small collection of pus. The sacro-iliac junction was extensively diseased. The joint was loosened, contained pus and sequestra. Another opening was found, and near the bottom of the sacro-iliac junction, at the upper margin of the ischiatic notch. The bony walls of the first, second, and third sacral foramina of the right side, were roughened and partially destroyed. The lower lumbar and upper sacral nerves of right side were compressed by the thickening of tissues, and the pressure of pus around them. The psoas abscess, in its passage underneath Poupart's ligament, ran along the course of the vessels, between the tendons of the psoas and iliacus internus muscles. Nothing abnormal was found in the interior of the vessels of the thigh, but there was considerable inflammation around them, uniting them together. The cellular tissue of the thigh was infiltrated by purulent matter, and some gas escaped on cutting.

Dr. Hamilton further remarked—

The following conclusions may be drawn from the case:—

1. Disease of the sacro-iliac junction may occur in a healthy person without being traceable to any special injury.

2. The disease may make pretty extensive progress without materially affecting the general system, and without causing much, if any, lameness, or distortion of the limb.

3. The abscess consequent upon the caries may follow the course of the psoas magnus, entering the sheath posteriorly where the fascia is weak, and present itself upon the front or inside of the thigh; it may penetrate the quadratus lumborum, and passing outside of the sacro-lumbalis and latissimus dorsi, open upon the back just above the crest of the ilium, or it may dissect up the periosteum and fasciæ, and present itself at the sacro-sciatic notch, in the rectum, in the vagina, or anywhere in the perineal region, but especially near the point of the sacrum.

4. By descending between the sheath of the psoas muscle and the muscle itself, and thus not involving the substance of the muscle, it may not cause pain when

the thigh is straightened upon the body, or give rise to any other symptom indicating the presence of the abscess in the vicinity of the psoas muscle. And, inasmuch as an abscess, arising from caries of any of those vertebræ from which the psoas muscle has its origin, almost uniformly divides the head of the muscle, and thus penetrates into its substance, sometimes destroying it so completely that nothing but the sheath remains; therefore it may be proper to conclude, that in the case of a well recognised psoas abscess, the ability of the patient to straighten the thigh before the body without pain or inconvenience, might be regarded as pointing to its origin in its last lumbar vertebra, or the sacro-iliac junction; and that this circumstance might sometimes be employed as a means of diagnosis between a psoas abscess, arising from caries of the last dorsal, and from the upper lumbar vertebra on the one hand, and a psoas abscess, arising from caries of the last lumbar vertebra, or caries at the sacro-iliac junction, on the other hand.

Unfortunately it does not appear that any practical deductions as to the treatment can be drawn from this case; unless it be that, inasmuch as the symptoms became rapidly more serious after it was opened, life might have been prolonged by having kept it closed. It is possible, also, that if the diagnosis had been made early, by rest in the recumbent posture, and other appropriate remedies, the disease might have been arrested.

The rapid swelling, the pain, and the death of the right limb may be ascribed to pressure upon the sacral nerves by the abscess at their roots; by inflammation, extending from the abscess connected with the psoas muscle to the neighboring absorbents, veins, and arteries, to thrombosis, or to septicæmia. One, or all, of these several causes must have operated.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

STATED MEETING, MARCH 4, 1867.

DR. SAMUEL T. HUBBARD, PRESIDENT, in the Chair.

THE PRESIDENT announced that it had been voted to grant certificates of membership to Drs. Watts, Cady Livingston, Gerardus H. Wynkoop, F. Munson Cone, Alonzo J. Cassidy, Max Herzog, Albert O. Treat, and John Sidney Warren.

DISEASES OF THE MONTH.

DR. DUNSTER, of the Committee on Diseases, reported that the total mortality, 1,719, of the four weeks preceding February 23d, was somewhat less than that of the month previous, and than that of the corresponding period of last year. Zymotic diseases accounted for about one-fifth of the deaths; and under this head was noted a slight decline in the fatality from scarlatina, typhus, and typhoid, with an increase in that from diarrhœal diseases; whooping-cough and measles had been very prevalent. Under respiratory diseases, pneumonia alone was charged with 149 deaths, and bronchitis with 67, though this showed little change from the preceding month. Children had suffered severely, one-fourth of the whole mortality belonging to infants under one year, and nearly one-half to children under five. A remarkable immunity attached to the ages from five years to twenty. Genuine typhus had appeared, during the month, in several distinct and even widely separated localities; but it was believed to be traceable, in every case, either to recently arrived immigrants or to their associates at the benevolent lodging-houses where they find shelter. A very mild form of typhoid had been, for some time past, prevailing along the western shore of the city, only two cases out of fifty-six resulting fatally. During December last there occurred an outbreak of this fever at the Deaf and Dumb Institution. The inmates were dispersed to their homes, and the disease proved thereafter quite tractable, none of the numerous patients succumbing to it. The Institution was closed, and thoroughly renovated at an expense of some $20,000; yet upon its re-opening, the first of February, the fever reappeared. It is said that the mattresses upon which the fever-patients had slept, were not disinfected except by exposure to the air, and also that the privies were left uncleansed. These statements, if correct, may account for what would otherwise seem an extraordinary tenacity of the fever-poison in clinging to its old haunts.

The President announced the death, since the last meeting, of Dr. Wm. E. Stillwell, a member of the Society.

CHOLERA: IS IT CONTAGIOUS?

DR. WM. C. ROBERTS read an elaborate paper upon "The Contagiousness of Cholera shown from its Analogy to other Epidemics and the Laws of Specific Poisons." The essay, which occupied about an hour and a half in delivery, reviewed the whole subject of the communicability of disease, the writer fortifying his positions by extracts from numerous authorities, and the citation of a number of cases. Any abstract must fail to give an adequate idea of the paper; but we subjoin the chief points of the argument, as far as possible in its own words.

Specific morbid poisons, while exhibiting individual differences in their mode of action and of propagation, which determine their specific character, are yet generically allied. All epidemic diseases are due to such poisons, and show a similar generic likeness, the morbific principle being in general reproducible in the bodies of the sick, and so becoming animal, zymotic, and contagious. Every specific zymotic epidemic is necessarily contagious. Cholera is clearly a specific epidemic, and we have, then, only to show it zymotic in order to prove its contagiousness; and this whether the zymosis be intra-corporeal or extra-corporeal (perhaps intra-aerial). For though we may be constrained to admit some meteoratious epidemic influence to account for its rapid diffusion, yet this influence must depend for its activity upon the specific germ, which, whatever its genesis and its means of subsequent reproduction and convection, is still the essential element of contagion. Now that cholera is zymotic we may infer from its analogy to other diseases universally recognised as contagious zymotici. If typhus and small-pox are zymotic, how much more must this be, which surpasses them, as it does all other epidemics, as well in the swiftness of its march as in the violence of its attack, and our powerlessness to cope with it.

As to the mode of elimination of the poison, it is probable that, as in typhus, it is excreted most abundantly by the gastro-intestinal mucous membrane; so that fomites soiled with the alvine discharges are especially liable to communicate the disease; while the germs from the desiccated dejections may be suspended in the atmosphere, rendering it infectious. But we cannot allow that this is the only mode of elimination, nor that infection may not find its way through other channels. Facts do not bear out the conclusion that cholera is not communicable even by contact between individuals.

It is possible that the cholera-poison may even now be, at times, produced *de novo*, as that of typhus is believed to originate from ochletic miasm. But more probably both these and other specific diseases are, in the cases of apparently spontaneous origin, developed

from their proper virus, long dormant, but suddenly brought to light and aroused to activity by favoring conditions.

Voted that the paper of Dr. Roberts be accepted.

PROFESSOR FLINT, in rising to discuss the subject, said, that owing to the lateness of the hour, he should speak briefly and only upon important points. He should use the term "contagion" in its broad and popular sense, to denote the communication of a disease by a morbid product, either palpable or impalpable, produced within the body, though it would be well to limit the term to communication by a palpable virus, reserving "infection" for that by a poison which eludes the senses. The term "portable," for which we are indebted to the late Professor Mitchell of Philadelphia, had always seemed to him very good and convenient to express a cause that may be transported by "fomites," using this word as applicable not alone to clothing, but to anything which may carry the poison.

In considering a question of this character, we must be careful to free ourselves from the influence of the views that may chance to be at the time prevailing. The popularity of a theory, even within the profession, is very fluctuating, and can furnish no ground for an opinion. For instance, in the epidemic of 1854, very few believed cholera contagious, while now a considerable number seem to hold it such.

He did not feel like accepting the argument of the paper just read by the distinguished gentleman, that, because cholera is specific and epidemic and zymotic, therefore it is contagious. Influenza, and various other zymotic affections, with those endemic and zymotic, like yellow fever or cerebro-spinal meningitis, would hardly be considered contagious. Nor must we judge of the contagiousness of this, or of any disease, from special isolated facts, such as had been cited. As in theology it is easy to prove any dogma by isolated texts of Scripture, so in medicine one may easily find facts upon either side of a question in dispute. The recent report of the Registrar of Vital Statistics, would furnish an apt illustration. The fourth of the early cases of the epidemic of last season is recorded (*Report of Metropolitan Board of Health for* 1866, p. 169), as that of "the fearless and strong woman who washed the soiled clothing and bedding of her brother-in-law," and the impression is left that, in the opinion of the Registrar, this was the cause of her attack. Now turn to page 271 of the same report, where, in the paper of Dr. Yale, we have an account of the number of cases which occurred among all who were engaged in washing the clothing upon Blackwell's Island. He says:

"At the asylum were employed about twenty washerwomen; of these one had cholera. This is only five per cent., or a considerably smaller percentage than among those not so employed. At the work-house twelve washerwomen died, their places being supplied by others; the total number being thirty-four. This proportion (35 per cent.) is somewhat heavier than among those who did not wash. At the Almshouse the precise number of washerwomen attacked is not stated, but the washing is chiefly done by the nursery women from the wards 45, 46, 47, and 48, which have been already mentioned as having but four cases in all, which is certainly below the average. At the Penitentiary I neglected to inquire upon the point. At Charity Hospital no washerwoman was seized. The amount of danger from infected articles would, in all probability, be very slight where disinfectants were freely used; but for the first few days of the epidemic this matter was, in the main, overlooked, and full play was then allowed for the action of any infectious material."

Dr. F. had been in hospital service during the epidemic of 1849, and could say positively that at the institutions with which he was connected, none of those engaged in washing the clothing of cholera patients were attacked by the disease.

It is essential to settle the principles upon which, by means of aggregated facts, the contagiousness or the non-contagiousness of a disease is to be established. He would enumerate a few of the most important:

A contagious disease extends from the localities where it becomes established, through the proximate localities; and though it may gradually extend to those more or less distant, yet, in a certain proportion of these instances, it should be practicable to trace the contagion. This is certainly true of most of those diseases universally considered contagious, as typhus and scarlatina. How with regard to cholera? Upon this point the earliest cases in an epidemic are of the greatest value. Referring again to the Registrar's Report (*Op. cit.*, pp. 167–171), we find the history of the first nine cases of the late epidemic in this district, with dates and residences as follows:

April 30. Woman, Ninety-third street and Third avenue, died next day.

May 2. Woman, 115 Mulberry street, recovered.

June 3. Man, 303 Broome street, died next day.

June 6. Woman, same place, died same day.

June 9. Woman, West Twentieth street, fully two miles from any of the preceding.

June 9. Man, Hester street, laboring at East River.

June 11 Woman, W. Thirty-fourth street, between Fifth and Sixth avenues, had been visiting near Pitt and Willett streets, died 13th.

June 13th. Man, 51 Cherry street, died same day.

Same date, man arriving from Troy, breakfasting near Greenwich and Liberty streets, and visiting in Waverley Place, died same day.

These places are certainly sufficiently remote from each other, and from any probable common source of contagion. Were this wide separation of the early cases characteristic only of the last epidemic, it would be less noteworthy; but it is unquestionably true of the majority of epidemics. The speaker had had occasion in 1849 to trace the history of the epidemic at Buffalo, N. Y., where he there found the first cases occurring almost simultaneously in localities so far apart that it would have been impossible to admit any connexion between them. So far then as this ground is concerned, we find no evidence of the contagiousness of cholera.

A second important ground of decision is to be found in the number of persons who, coming from an infected district to a healthy one, are there attacked and become foci of infection. Now it is doubtless possible to collect a number of strong instances that seem to sustain the doctrine of contagiousness. But such cases are very few as compared with the great number where, under like conditions, no such result follows. It is true, this may be called negative evidence; but then it is possible for a vast amount of such evidence to outweigh positive evidence of doubtful character. For the cases relied upon by the contagionists are perhaps all capable of explanation by the theory of the portability of the special cause, without admitting its production in the human body.

Again: Of those brought into personal contact with the patients, is a larger proportion attacked than of those not so exposed? This Dr. F. deemed one of the strongest points; and he believed he was perfectly correct in saying that, taking a large collection of instances, a greater proportion of those brought into contact with the cholera patients escape the disease, than those similarly circumstanced who have no connexion with such patients.

Certain points connected with analogy are of some moment. Contagious diseases, except those of parasitic origin,—all zymotic contagious diseases, that is,—give, as a rule, immunity from a second attack; though this is also the case with some diseases not contagious, like yellow fever. If cholera were contagious, we should, then, expect this immunity as the law; but it appears to give us no such protection. Again, contagious diseases of zymotic character cannot, as a rule, be arrested. Probably no one present would doubt that we do have the means of arresting cholera; that it may be prevented by very simple means in the premonitory period; and that we are able sometimes to arrest it after it is fully developed. Another point would be barely mentioned: A disease properly contagious is not limited in its duration in a given place by any law. It continues so long as there are fresh subjects for it. But it is believed we all know the case is different with regard to cholera, which generally continues three or four months and then disappears.

In closing, Dr. Flint referred again to the Report of the Board of Health, in regard to the prophylactic measures employed under its direction. It is well known that disinfectants were used more fully and more promptly during the last epidemic than probably ever before; and the facts would seem to show that by their means we have the power not only of removing the predisposing causes of cholera, but even of destroying the special cause itself. This must not be construed into an admission of contagiousness; for there is no reason to suppose that the disinfectants may not be as efficient against poisons not derived from the human body as against those which acknowledge this source. If it be true that we have learned how to prevent this disease, we have made an immense advance.

Dr. Marx Herzog insisted that the question was one demanding the most rigid scientific investigation, and must be determined by reference to certain great natural facts which could only be settled by experts. The authority of such *quasi* scientific bodies as the International Commission at Constantinople was quite valuable; while the highest importance attached to the labors of men like Pettenkofer and Drasche, whom he was astonished not to have heard named by either of the gentlemen. To these men, indeed, more than to any one else, are we indebted for everything positively known upon the subject. Considering the discoveries already made, he had no doubt that within our own lifetime we should have the miasm made sensible to chemical or microscopic observation. He then gave an exposition of Pettenkofer's well known theory: that for the production of cholera the first requisite is the specific cholera germ. This exists most abundantly, though perhaps not solely, in the discharges of patients affected either with cholera or with choleraic diarrhœa. These discharges are harmless until they have undergone a certain putrefactive process, and again after this process has progressed beyond a certain limit—as clearly proved by Thiersch's experiments upon animals. The second requisite for the disease to become epidemic, is a favoring condition of the soil, which must be porous, and subject to changes of level in the subsoil water (ground-water). It is especially after the subsidence of this water that the organic matter left behind is in the proper state for the zymotic reproductiou of the poison. And here, as in the case of the discharges, the fermentation, once established, runs a definite and limited course, during which alone are the telluric emanations noxious. This theory was based upon very extensive observations made by the most competent men throughout the whole continent of Europe, except in France. Dr. H. regretted that similar observations had not been made here, during the late epidemic, particularly in regard to the varying level of the ground-water, which served to explain so many apparent anomalies. This point was of equal interest in epidemics of typhus. He exhibited a chart showing the relation of the level of the subsoil water to the prevalence of typhus, in a given locality, for ten years, which gave results strictly accordant with the above views. He was happy to be able now to correct the false impression that these fundamental laws had found an exception in a certain part of Austria; and the puzzling case of the pilot of the England had at last found a solution in the fact that his boat was towed near the ship's drain-pipe, where he was necessarily exposed to the effluvia from the decomposing discharges. Statistics of 15,000 or 16,000 cases in Germany showed that cholera does not twice attack the same person during the same epidemic. He would advise a man who had had diarrhœa, in a house where cholera had prevailed for sixteen or eighteen days, not to remove; as in that period the poison loses its power. For lack of time he would not read the paper he had prepared, but he had said what he deemed most essential.

Dr. Thoms called attention to the fact as shown by a chart prepared for another purpose, that in the twelfth ward, where the cholera-hospitals were located, the ratio of cholera-mortality to the population was nearly as great as in the fourth and sixth wards, where the class of people and the hygienic conditions were esteemed the worst. The cases in the hospitals themselves were properly accredited to their respective wards.

Dr. Alex. H. Stevens thought the discussion mainly a dispute about words. It does not follow, because cholera may not be communicable in the same manner as small-pox, that it is not contagious. As well deny the contagiousness of syphilis, because we do not catch it in walking the wards. Every poison has its own laws of communicability, which must be met, for it to produce in any case its specific effects.

The President announced that at the next meeting Dr. Fowler would read a paper upon a subject connected with cholera.

By courtesy of the Society, Dr. Hubbard, of Illinois, exhibited a truss of his own invention, for which he claimed several points of superiority.

The meeting then adjourned.

EAST RIVER MEDICAL ASSOCIATION.

Stated Meeting, March 5, 1867.

Dr. V. Morse, President, in the Chair.

(Continued from page 67.)

CERTAIN POINTS IN THE TREATMENT OF SCARLATINA.

Dr. Buttles related a case where the bisulphite of soda was used as a prophylactic in scarlatina, and which, in the main, corroborated the testimony given in its favor by Dr. M. L. Smith.

Dr. Newman, however, regarded its effects as more than uncertain.

Dr. Buttles urged early and continued greasing during the progress of the disease, as a very essential element in its treatment. This method is reputed to be much relied on by German practitioners.

Dr. T. Nichols regarded the use of Dover's powder as admissible when great jactitation or troublesome delirium was present, the only contra-indication being active congestion of the brain.

Dr. Thoms, while he questioned its prophylactic properties, was disposed to pronounce belladonna,

which according to some exerted its power upon the pneumogastric nerve, a very valuable anodyne, and one not to be ruthlessly discarded simply because it had once been much lauded by "irregulars." The fact of its having been overrated should not prejudice us against its more humble claims.

Dr. M. L. Smith then gave the history of two cases of extensive abscess on the anterior and lateral surfaces of the neck, after scarlatina.

The meeting then adjourned.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Conversational Meeting, March 13, 1867.

Dr. Andrew Nebinger, President, in the Chair.

(Specially Reported for the Medical Record.)

THE STATUS OF FEMALE PRACTITIONERS OF MEDICINE.

The report of the Committee, to whom had been referred the subject of a resolution laid over from the last meeting of the Medical Society of the State of Pennsylvania, held at Wilkesbarre, Pa., in June last, to the effect that nothing in the resolution of 1860, declaring it unprofessional for members to consult with the professors or graduates of Female Medical Colleges, as at present (1860) organized, should be so construed as to prevent members from consulting with properly qualified female practitioners, who strictly observed the code of ethics, was read by the chairman, Dr. D. Francis Condie, and is as follows:—

"*To the Philadelphia County Medical Society.*—The subject submitted for the consideration of your Committee may be comprised in the following question, namely:—Is the recognition of female medical graduates, by our profession, proper and expedient?

"It cannot be denied that there are in our midst women of fine natural abilities, cultivated by a thorough liberal education; nor will it be doubted by any one that, were one of this class of women to be thoroughly instructed in the institutes and practice of medicine, she would be as likely to become as successful a practitioner of the healing art as any male graduate; and were a woman thus qualified to confine herself to the investigation and treatment, especially, of the diseases of her own sex, and of children, we do not believe that the association with her at the bed-side of the sick would be objected to by any liberal-minded practitioner of the other sex. But to inundate our profession with a host of females possessed of no higher qualifications, professional or ethical, than are possessed by the graduates of badly organized and irresponsible schools, cannot be too strongly deprecated. There are just grounds to believe that such will most surely be the case as schools for the manufacture of female doctors multiply, and their benches become thronged by women who are prompted to the pursuit of medicine by no higher motive than what results from a feeling that it is one more respectable, less confining, and more remunerative than any of the ordinary pursuits that are now open to them.

"Even to those ladies who are conscious of possessing all the qualifications, intellectual and educational, to enable them to enter, with a fair prospect of success, upon the study and practice of the healing art, we would say, "Pause before you assume the toil and anxious cares, the heavy responsibilities, incident to the life of a physician. Recollect, also, that in devoting your days to the practice of medicine, you must necessarily forego that high and noble mission, for the fulfilment of which you were destined by your Maker. You cannot hope to become the central sun of the domestic circle, diffusing throughout it a genial light, and warmth, and beauty; you must give up the pleasing task of developing—as none but a mother can—the physical, moral, and intellectual faculties of the young; and of acting out your appropriate rôle of becoming at all times, and in all things, a help meet for man. To practise medicine faithfully and successfully, demands a concentration upon the work of the whole mind—of the entire life. It will allow of no other pursuit being carried on in connexion with it; scarcely of any turning aside for necessary relaxation and repose.

"There is another important preliminary to be disposed of by the female before it will be prudent for her to assume, as the pursuit of her future life, the arduous, never-ending task, the anxious, exacting duties of a medical practitioner; and that is, to determine whether her physical strength, and the physiological peculiarities of her organization, are such as will enable her to fulfil, faithfully, the duties of a medical practitioner, without incurring the risk of an early loss of health, leading, it may be, to an early extinction of life.

"In disposing of the question submitted for the consideration of your Committee, the fact must be taken into consideration, that female practitioners, authorized by the authority of the State, already exist, with a clear prospect that their increase in the future will be far greater than it has been in the past. In view of this fact, your Committee would respectfully suggest whether the wisest course for us to pursue would not be to offer every encouragement and facility to insure to the female graduate such educational and professional acquisitions as will enable her to enter with safety and with credit upon the practice of medicine.

"We confess that we are opposed to female medical colleges as now organized. If we are to have female physicians, let them emanate from the same schools at which our male physicians receive their professional education. Our leading medical colleges are constantly embracing in their faculties the best talents of the country, enlarging their courses of instruction, and elevating their requisites for graduation. Let these advantages be extended freely to female students. If objection is made to females being taught in the same classes with the male students, they may be formed into separate classes, and receive instruction at hours appropriated especially to them.

"Your Committee trust that the medical profession will never approve of a recognition of every female graduate, without discrimination, as a legitimate member. Your Committee believe, nevertheless, that it would be a judicious measure—one indeed of policy and of justice—to draw a broad line of demarcation between the worthy and the unworthy, the competent and the incompetent of these females who come forward as practitioners of medicine, and, while without hesitation the unworthy and the incompetent are repudiated, the hand of fellowship be extended to the opposite class, in all good faith; confirming them thus in an honorable career, and at the same time granting to them the same rights and privileges that are secured by our code of ethics, to every member of the profession, and subjecting them to the same penalties for any infringement by them of the provisions of that code.

"When we shall be prepared to draw such a line of demarcation, and by what authority it shall be established, are questions which cannot be definitively settled until all necessary regulations in respect to the education of female aspirants to the doctorate in medicine shall be established, and the nature of the security that shall be required of them for a strict compliance on their part with such regulations, shall be settled.

"Having thus presented very candidly their opinion on the subject submitted for their consideration, your Committee would present for your adoption the following resolution, namely:

"*Resolved*, That the Philadelphia County Medical Society cannot consent to the repeal of the resolution passed by the Medical Society of the State of Pennsylvania, at its session of 1860, in reference to 'the graduates of Female Medical Colleges, *as at present constituted;*' and they hereby instruct the delegates from the Society to the next session of the State Society, to use all honorable means to prevent the repeal of the said resolution, which they believe to be as loudly called for now as at the period when it was passed.

"All of which is most respectfully submitted by

"D. FRANCIS CONDIE,
"JOHN F. LAMB.
"A majority of the Committee.

"PHILADELPHIA, March 18, 1867."

A very animated and prolonged discussion ensued when the resolution appended to the above report came up for consideration. The report itself gave apparent general satisfaction. Every speaker who referred to it commended it, and not a single voice was raised deprecatory to it. The speakers seemed divided into three classes: those totally opposed to female medical practitioners, under any circumstances; those willing to extend to them the hand of fellowship at once; and those who were undecided in regard to the subject, and, although disapproving of female practitioners in the abstract, were willing to admit the expediency of receiving them, either at once, or at no distant period, when some standard of professional requirements should be adopted. Then came up the question as to the nature of the standard to be required. Some said, let us receive graduates of schools which may be hereafter recognised by the American Medical Association. To this, answer was made that there is but little chance for a fair hearing on the part of the female practitioner, for neither she nor those associated with her could be received as a delegate; besides which, the code of ethics, in prescribing the requisites for consultation, implied that the status of a physician should be determined in the community where he resided, rather than by the American Medical Association. It was also urged that the resolution opposed the liberal spirit of the report. It was also urged in opposition to the adoption of the resolution appended to the report, that to a certain extent the disability existing in 1860 did not exist in 1867, it being represented that the professors of one female medical college in the country, at least, were regular graduates, and otherwise than in their connexion with the college, in good standing; and that the requisites for graduation by that institution were as stringent in every respect as at the leading medical schools in the country. That therefore, in fact, this college was now differently organized from what it had been in 1860, and that, therefore, literally, that school was no longer subject to the discipline of the resolution. It was also urged in the same connexion, that *necessity*, and not choice, had compelled the female colleges to put up with the best instructors they could obtain; for again and again had female students knocked for admission at the doors of our regular medical institutions, and as regularly had they been refused. That they were anxious to become thoroughly instructed, and it was their misfortune and not their fault that they received instruction of inferior quality.

It was proposed to substitute for the resolution of the Committee, one approving of the adoption of the resolution offered by Dr. Mowry at the State Society, permitting consultation with properly qualified female practitioners who observed the code of ethics; but it was at once met by the objection of an unwillingness to permit any man to judge for himself as to who was or who was not properly qualified; and that the standard of such qualification must be decided by a competent medical body, and not by the individual.

At length, after much discussion pro and con., the following resolution was offered:

"Nevertheless, nothing in the foregoing resolution shall be construed to forbid any member of this Society from consulting with any female practitioner, who shall be declared by the American Medical Association as regularly educated, and who gives sufficient evidence of strict adherence on her part, to the code of medical ethics."

SPECIAL CONVERSATIONAL MEETING, MARCH 20, 1867.

THE DISCUSSION ON THE STATUS OF FEMALE PRACTITIONERS OF MEDICINE was continued. A preamble and resolutions were offered as a substitute for the resolution under consideration, the principal feature of which was, that the Female Medical College mentioned upon the previous occasion, being at present a regularly organized institution, requiring the same qualifications for graduation as the regular medical colleges, their professors and graduates should be entitled to recognition in consultation. Under the impression that all the professors of this institution were in good standing, and observed the code of ethics, it is likely that the preamble and resolutions referred to, and of which it is unnecessary to be more explicit in this report, would have been passed after undergoing some modifications. But the exhibition by one of the members of a printed circular of one of the professors of this Female Medical College, calling the attention of the public to the superior and infallible superiorities of certain cholera remedies, and other secret remedies, prepared solely by himself, and calling attention to the fact that he was prepared, at certain office hours, to be consulted, in certain languages, upon any diseases incident to either sex, etc., completely nullified the effect produced by the preamble, and the discussion which had thus far followed it, and the resolutions were lost without a dissenting voice.

Then the following preamble and resolutions were offered by DR. BELL, and adopted unanimously:—

WHEREAS, in looking to the usefulness and dignity of the profession which are inseparably connected with the welfare of the community, we are met with very grave objections to women taking on themselves the heavy duties and responsibilities of the practice of medicine. Their success in the walks of general literature, and even, in some instances, of science, which allow them a choice of time and season for intellectual labor, cannot be adduced as argument in favor of their ability to bear up under the bodily and mental strain to which they would be unceasingly subjected in this new vocation. The physiological peculiarities of a woman, even in single life, and the disorders consequent upon them, cannot fail frequently to interfere with the regular discharge of her duties as physician in constant attendance on the sick. How much greater must be the interruption to her duties if she enters the married state, and becomes a mother and nurse. Her delicate organization, and predominance of the nervous system, render her peculiarly susceptible to suffer, if not to sink under the fatigue and the moral shocks which she must encounter in her professional rounds. Man, with his robust frame, and habitual self-command, is often barely

equal to the task. The home influence of women is one of the greatest benefits growing out of Christian civilization. More especially is this manifest when we look at her as head of the household, a helpmate to her husband, and the confidant, guide, instructor, and loving friend of her children, whose future happiness and respectability so much depend on her tuition and example. What would be the state of the household, what the present condition and future prospects of the children, deprived to a considerable extent of their natural guardian, who would be engaged all day, and not secure against calls in the night, in the service of the sick? Nor when at home, can the mother, worried, and fretted, and anxious about her patients, be in a fit frame of mind to interchange endearments with her beloved little ones, to receive their confidence and offer advice.

Once embarked in the practice of medicine, a female physician will not long confine herself to attendance on persons of her own sex; and it is easy to conceive the embarassments on both sides, which would be met with in her visiting and prescribing for persons of the opposite sex. If her services be restricted to the female portion of a family, there must be a male physician to attend on the males; and thus there will be constantly two physicians in the regular service of a family, with all the chances of counter-prescription and advice, and breach of ethics, misunderstanding, and heart-burnings. With this new element of probable discord, it will be doubly difficult for us to conform to the code of medical ethics. If a female physician be once received in full standing and professional intercourse, by consultation, or otherwise, with a physician of our own sex, the greatest latitude will be allowable in the statement of the case, its symptoms and causes, and question of treatment, therapeutical and psychical. Will woman gain by forgetting to blush, and by discussing every topic as it comes up with philosophic coolness? or man be improved in the delicate reserve with which he is accustomed to address women, both in the sick-room and elsewhere? The limits of modesty once passed in this professional intercourse, is there no danger of further advances, in which a sensitive nature would repel as familiarities, what under other circumstances would be inadmissible?

Could women be induced to see the true line of duty in relation to medical study, it would be to learn preventive medicine, and acquire a suitable knowledge of physiology and hygiene, so as to be able to preserve their own health and that of their children; and to inculcate on the latter the close connexion between the physical and moral well-being of our nature. The field is large, and its cultivation would richly repay the laborers in it.

In no other country than our own is a body of women authorized to engage in general practice. The specialty of midwifery practice in France is hedged in by restrictions which call for the assistance of medical men in every case of difficulty or doubt.

Moved by these considerations, be it therefore

Resolved, That in conformity with what we believe to be due to the profession, the community in general, and the female portion of it in particular, we cannot offer any encouragement to women becoming practitioners of medicine, nor can we consent, on these grounds, to meet in consultation such practitioners.

PROCEEDS OF THE BALL IN AID OF THE NURSERY AND CHILD'S HOSPITAL.—The Treasurer of the Nursery and Child's Hospital has received the sum of $12,383 59, being the net proceeds of the ball given for the benefit of that institution on the 4th of March last.

NEW YORK ACADEMY OF MEDICINE.

STATED MEETING, MARCH 20, 1867.

DR. A. C. POST, PRESIDENT, in the Chair.

DRS. JAMES ANDERSON and CHARLES A. BUDD presented to the Academy several volumes, confided to them for that purpose.

THE SOURCE OF UREA.

DR. JOHN C. DRAPER called the attention of the Fellows to the corroboration of views regarding the source of Urea which had been advocated by him in a thesis some ten years ago. The opinion then expressed resulted from a series of experiments, which had covered a previous period of two years. About this time he had also published in the old *Journal of Medicine* a paper, in which he maintained that the "Urea merely represented the access of nitrogenized material consumed, and was not indicative of the amount of muscular action." In 1860, May 20, he read before this body another paper, in which it was shown that the effete materials arising during muscular action are evacuated as insensible perspiration, by skin and lungs, and that the loss by these channels is much greater than by the kidneys. He was thus explicit in his statements, because the doctrines then enunciated, and which had now begun to excite attention in Europe, were in reality directed against Lehman's theory that urea was the product of muscular disintegration. Drs. *Nick* and *Wislicenius* now also assert that muscular force is the result of oxidation of fats. They regard a bundle of muscular fibres as a species of machine, formed of nitrogenized material, as an engine is made of iron and brass. As coal is the origin of force in the latter, so the combustion of fat is the producer of force in the former; and as in the engine there is a slow, gradual rust and wear taking place, so in the muscular fibre there is also a similar destruction of material which bears an infinitely small ratio to the force produced. The analogy instituted was certainly a beautiful one and exceedingly suggestive.

DR. HUBBARD'S TRUSS.

DR. N. W. HUBBARD, of Illinois, was then introduced, and adjusted his truss upon a patient afflicted with double inguinal hernia. He claimed that his instrument had above all others the advantage of simplicity and perfect adaptability to every variety of condition, stage of development, and complication of hernia. The pad, which was of wood, might be adjusted to any angle, so as to fit the corpulent or spare, while the pressure was capable of a like variation. It also possessed a retentive power, which might be rated as three times greater than the actual pressure.

The Truss will not cramp or move when the patient gets into *any* position, and it is easy and pleasant to wear, as a necessity, resulting from its perfect adaptation.

Owing to the fact that the girdle was made of steel, which was annealed to within a short distance of the pad, the instrument could, with a reasonable amount of strength, be moulded to any shaped pelvis. The periphery of the pad, also, as in the case of femoral hernia in the female, might be pared down to meet the emergencies of the case. In fact, any necessary or desirable alteration in size or shape of truss, position of pad, or pressure, can be made at pleasure, so that the patient will feel that no further improvement is requisite, or can be made.

DR. HAMILTON said that no new principles had been involved in the construction of the truss exhibited. The

pad was of the old Chase pattern, and the tractable girdle had likewise been previously used. But he, for one, had always avoided the encouraging of patented instruments, and to this objection the present truss was open.

Dr. Joel Foster professed to have made himself familiar with almost every variety of truss, and had seen the success of Dr. Hubbard's instrument in one or two cases. He had been favorably impressed with its peculiarities, and had therefore invited the gentleman to exhibit it before the Academy.

Dr. Hamilton had intended no personal discourtesy; he merely battled for the principle, and claimed to represent his profession. He thought that all medical bodies should be very chary of their endorsements of any article, on account of their liability to take the form of advertisements. He thought that all were apt to be misled by the expertness of instrument-inventors, and in this way were led to endow the instrument with superior qualities. It was thus that the general practitioner so often failed in the application of these appliances. In short, it was not the perfection of the instrument, but the skill of "*the expert*," in adjustment, which wrought the wonder.

THE STATE MEDICAL SOCIETY.—CRIMINAL ABORTION.

Dr. James Anderson, as one of the delegates to the Medical Society of the State of New York, reported that the session had been marked by the best of feeling. The meeting, he stated, was large, and according to the impressions of numerous delegates, more interesting than any previously held. As an episode in the transactions, he would mention the fact, that a prominent senator had suggested to him an official recommendation on the part of the Society to the State Legislature, that the circulation of infamous circulars in the community be suppressed by law. He (the senator) was satisfied, upon his own convictions, that these exerted the most deleterious influence. The doctor was himself pained at the enormous extent to which criminal abortion prevailed, and hoped that the profession might be purged of those members, who, tested by the association of names with the practice, had forfeited their position in a most honorable calling. He feared, too, that notwithstanding the incompleteness of testimony, there was no absence of guilt; and that the expression of the disappointed applicant, "If you will not, so-and-so will," was founded on something more than pure fiction. This was the class, he apprehended, that would bear watching.

The Academy then adjourned.

Correspondence.

THE LATE DR. T. K. CHANDLER.

To the Editor of the Medical Record.

Sir—I find in the number of your journal for March 1st a notice of the death of Dr. Thomas K. Chandler, Act. Passed Asst. Surg. U. S. Navy.

Dr. Chandler was a few years ago so well and favorably known, by many of the profession, in your city, that some more marked notice of his death than a mere news item, seems but due to his memory.

He came to New York from Fredonia, Chautauque co., some time in 1860, and matriculated at the College of Physicians and Surgeons.

An illustration of the determination to overcome all obstacles, which was characteristic of the man, will be found in the fact that while attending the lectures he was suffering so severely from necrosis of the femur as to be obliged to use two crutches constantly. I mention this, too, because it will recall him at once to every member of the classes of '60, '61, '62. On graduating in 1862 Dr. Chandler became an interne of Bellevue Hospital, and on the expiration of his term of service, April, 1863, entered the volunteer navy.

He was almost immediately ordered to the Steamer Princess Royal, and served on her in the Mississippi and Gulf Squadrons until the close of the war. He was afterward assigned to duty at the Washington Naval Hospital, and finally was ordered to the Penobscot, on which vessel he laid down his life in performance of his professional duties. During his residence in Bellevue, his professional enthusiasm, his genial disposition, and, more than all, his irresistible humor, won from each one of us, his associates on the resident staff, a most hearty recognition of his worth; and now that he is gone from us, no one of us but will remember him with pleasure and regret his early death.

I am, sir, yours truly,

W. C. Pryer, M. D

New Rochelle, March 5, 1867.

MEDICAL ADVERTISING.

To the Editor of the Medical Record.

Sir—In the Medical Record of March 15, appeared an editorial headed "Medical Advertising again," referring to the use made of my name in a popular newspaper.

I had considered it unnecessary to notice the article as it appeared in the newspaper, well knowing that my associates and scientific friends were fully aware that this "quasi advertisement" was not sanctioned by me; and that even a disavowal under my name would subject me to further suspicion of advertising. But seeing your notice of it, placing me in such an unenviable and unfair position, I gladly accept your invitation to disavow any such use of my name as was there made.

My whole duty in this matter is to give you the facts and assure you that, if the article in the *Eagle* has pained you as a medical journalist, this use of my name has been much more painful and distressing to me.

A report of the case which I had presented to one of our medical societies, served for the "extract from her physician's diary." As for adding the "endorsement of" my "medical name and reputation," this I have scrupulously withheld, as is well known by the medical gentlemen who have seen the case with me.

You must be aware how difficult it is to keep a case so unusual out of the hands of reporters, and you must also appreciate the unpleasant and trying position of the physician in charge. I have been accused of believing in spiritualism and clairvoyance, of being myself a humbug and humbugged. I have been pursued by reporters, strangers, and physicians (male and female), for the particulars of this case, for months. But in every way have endeavored to keep it as professional as possible; and now that the case has so many times been made public, should not be held responsible for anything but my own acts. I appreciate the sympathy expressed in your criticism, and can only say that, in the discharge of my duty, when the proper time comes, I shall be glad to report the case to the profession generally as I have already done partially.

Should you be disposed to set me right before the readers of The Record by publishing this note, or any portion of it, you are quite at liberty to give my name. But in order to avoid even the appearance of further advertising myself in connexion with the matter, my own preference would be to omit the name as you did.

Very truly, * * *

Medical News and Items.

PERSONAL.

Brevet Lieutenant-Colonel W. R. Dewitt, Jr., Surgeon in Chief of the Freedmen's Bureau for the District of Maryland, has been relieved from duty at headquarters in Baltimore and ordered to report to the Assistant Commissioner at Louisville, Ky., for assignment to duty.

Surgeon George Peck has been ordered to report for duty April 1, at the Navy Yard, N. Y., vice Surgeon C. Eversfield to be detached.

Surgeons L. R. Hunter and J. M. Greene have been ordered to duty as examining surgeons to the medical board at the Philadelphia Navy Yard.

Passed Assistant Surgeon John H. Murphy has been detached from the Lancaster and placed on waiting orders.

Passed Assistant Surgeon J. Buckley has been ordered from the Lancaster to the Constellation.

Surgeon Elisha Griswold, United States Volunteers, mustered out of service, to date March 18, 1867.

Augustus T. Peck, M.D., has been appointed an Assistant Surgeon U. S. N. Commission to date from February 25, ult.

Dr. Russell B. Brownell of Sharon, Conn., died of phthisis on the 27th of January, at a place about twenty miles above Edfou, on the river Nile in Upper Egypt.

Dr. John Galvan, an Alumnus of the College of Physicians and Surgeons, N. Y., class of 1855, died in this city of acute phthisis, March 28, in the 33d year of his age.

Delegates Elect to the American Medical Association.—*From the Medical Society of the County of New York.*—Drs. Lewis A. Sayre (*Chairman*), Joel Foster, William N. Blakeman, Thomas C. Finnell, Samuel T. Hubbard, James Kennedy, H. Mortimer Brush, John P. Garrish, Thomas S. Bahan, Edward Bradley, James J. Connolly, Henry S. Downs, Louis Elsberg, Horace P. Farnham, Edward Fowler, N. Marsten Freeman, Abbott Hodgman, E. Lee Jones, B. M. Keeney, Wm. B. Lewis, William M. McLaury, Robert Newman, Wm. C. Roberts, Stephen Rogers, Anthony Ruppaner, Edward H. M. Sell, Gustavus S. Winston.

From the N. Y. Academy of Medicine.—Drs. James Anderson (*Chairman*), Jas. L. Banks, Edwd. L. Beadle, Mark Blumenthal, Henry D. Bulkley, Fred A. Burrall, John Byrne, John C. Draper, Wm. H. Draper, DeWitt C. Enos, Joel Foster, Elisha Harris, Max Herzog, J. Foster Jenkins, E. S. F. Arnold, Joseph Kammerer, Ernst Krackowizer, John Ordronaux, Samuel S. Purple, Benjamin I. Raphael, Gouverneur M. Smith, S. Fleet Spier, Edward R. Squibb, Alfred Underhill, Moses D. Van Pelt, Lothar A. V. ss, and Henry W. B. Woodhull.

From the East River Medical Association.—Drs. Verranus Morse, John Hart, John Shrady, and Montross L. Smith.

From the N. Y. Medical Union.—Drs. E. Lee Jones and Stephen Rogers.

The Rinderpest in France and Belgium.—The Department of State has received a despatch from the United States Legation at the Hague, dated March 16, in which the writer says: "Since my last letter the rinderpest has spread into Belgium and France. The report of its progress in Holland from the 5th of January to the 17th of February, shows a decline from week to week. The number of cases during that period was nearly 18,000; deaths, 7,175; slaughtered, 4,441; being a total loss of 11,596."

Army Medical Museum.—The Acting Quartermaster-General, D. H. Rucker, has issued an order authorizing officers of the Quartermaster's Department, in charge of the Government trains returning from the frontier and other remote points, upon the requisition of medical officers, to furnish transportation by such trains for collections of specimens for the Army Medical Museum, when such transportation can be furnished without injury to the public service.

Sudden Death in a Dentist's Office.—In a recent number of the *Medical and Surgical Reporter* an account of the following curious case is given:— Edmund Kerosin, a young man about twenty-three years old, entered the office of Dr. Ralph Lee, a dentist of this city, to have a tooth extracted. Anæsthesia was produced by nitrous oxyd gas, a cork having been placed between the teeth to keep the mouth open. As the tooth was extracted, we understand, it slipped from the forceps, and with the cork was drawn into the mouth. The tooth was subsequently thrown up from the stomach, but the cork—which does not seem to have been missed—entered the larynx, and by its presence there caused suffocation and death in an hour. A post-mortem revealed the presence of the cork in the larynx and the cause of death. This case, and its lamentable result, should serve as a caution to those who employ such adjuncts in the dental laboratory; and the physician who may be suddenly summoned to patients in a dentist's office, should bear in mind the possibility of an accident like this, and be prepared to open the larynx, if need be, which in this instance would in all probability have given instant relief, and saved the life of the young man.—*Medical and Surgical Reporter, February* 2.

Hudson River State Lunatic Asylum.—The Board of Managers of the Hudson River State Lunatic Asylum met at the Morgan House, Poughkeepsie, N. Y., and elected Mr. Abiah W. Palmer, of Amenia, Dutchess county, President; and Dr. J. M. Cleaveland, Medical Superintendent. Preliminary arrangements were also made to receive plans and specifications for the erection of the edifice.

Dr. David Livingston, the celebrated African explorer, it is now definitely ascertained was murdered by a roving tribe of Africans, about the 25th of October last. He was last heard of at "N'Doude," at the confluence of the Novuma and Niende. The Hon. Edward D. Ropes, United States Consul, writes from the island of Zanzibar, under date Dec. 9, 1866, as follows: "We have information that he proceeded further west to Mataka, a Miao chief, who gave presents of cattle and food. At this point the Indian sepoys remained behind and have since returned to Zanzibar. From Mataka to a lake was eight days' march. On crossing a wide water in Canves, they followed the border of the lake for several days, and thus struck inland. They were suddenly attacked in a bush country, about nine A.M., by a band of Mavite. Dr. L. killed the most forward of the attacking party, but was surrounded and cut down by one blow of a battle-axe, which cut half through his neck. Beyond this we have no details, for those who returned were the first to flee. Almost all who stood near Dr. L. were killed, although they seem to have done considerable with their rifles."

Original Communications.

FIVE UNPUBLISHED CASES OF LIGATURE OF THE SUBCLAVIAN ARTERY, FOR AXILLARY AND SUBCLAVIAN ANEURISM,

By WILLARD PARKER, M.D.,

PROF. PRINCIPLES AND PRACTICE OF SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

Case 1.—A. R., æt. 31, a man of good constitution, fell down a passage-way on the 5th of February, 1849, and a wooden pencil, which was in the side-pocket of his coat, was forced up into the right axilla, producing a wound of the axillary artery. In a few days swelling appeared in the situation of the wound, accompanied with pulsation. On the 18th, some hæmorrhage occurred through the wound in the axilla. It was proposed by the physicians in charge to effect a cure by pressure, but hæmorrhage repeatedly recurring, that plan was abandoned, and on the morning of the 23d I was sent for to ligate the subclavian artery. I performed the operation in the usual way, and placed a ligature upon the artery in its third stage.

On the 4th of March there was a return of hæmorrhage from the wound in the axilla. No pulse at wrist.

On the 6th, there was a recurrence of hæmorrhage ad ℥ xx; on the 8th, there was oozing throughout the morning and a pretty free hæmorrhage at one o'clock. Shoulder livid, hand and arm cold but not numb, tongue moist, no appetite. On the 9th, I cut down upon and freely laid open the aneurism. The wound in the artery being searched for and found, two ligatures were placed, one on either side of it. The ligatures came away on the 18th day, everything progressed well, and the patient finally recovered with the loss of the hand.

Case 2.—J. F., æt. 32, was admitted into the New York Hospital, December 5, 1859. He stated that nine weeks ago at sea, in attempting to step upon a water-cask, he missed his footing and fell a distance of four feet to the deck, striking on his right shoulder. He thought that he had simply received a sprain, but the next day the arm began to swell, was painful and ecchymosed. There was a throbbing in the axilla and pain extended down into the hand. In the course of the week a tumor made its appearance in the axilla, which slowly increased in size. Four days previous to admission, in lifting a bucket of water, he felt something give way in the tumor, the effort being followed by increased throbbing and pain down the arm.

The patient looks anæmic, but his general health is tolerably good. The right arm hangs powerless by the side. The hand and arm are of lower temperature than natural. The shoulder is somewhat elevated, and in the axilla is discovered an ill-defined, pulsating tumor. Pressure made upon the subclavian artery stops all pulsation and bruit in the tumor.

December 13.—I tied the subclavian artery in its third division, in the usual manner.

December 14.—Patient slept well during the night. This morning there is some heat of skin; pulse 96°, feeble.

December 15.—This morning he had a severe rigor, followed by fever and profuse sweating; pulse 100; more feeble. Complains of nausea; tongue coated. This afternoon he had another chill, followed by fever and sweating.

December 16.—Did not sleep last night; complains of pain in head and shoulder; surface warm, pulse 96; very weak. This morning he had a slight chill. Four o'clock p.m., he had a severe rigor, followed by fever, sweating, and delirium. During the evening and night he sank, and on the morning of the 17th he died.

At the autopsy, the rupture of the artery was discovered just beyond where the vessel emerges from between the two trunks of the median nerve. Some clotted blood was found in the tumor, but it was mainly fluid. The lungs, liver, and intestines healthy. Heart fatty, soft, dilated and flabby. No clots in any of its cavities. No clot in any of the large vessels. Kidneys fatty. There is no record of the urine having been examined.

Case 3.—J. D. æt. 39, seaman, was admitted into the New York Hospital, October 30, 1860, and gave the following history: Six years ago, while in China, he contracted syphilis, and was treated by mercury. During treatment he took cold, and lost the use of his limbs, and it was three months before he recovered from the paralysis. He is now suffering from secondary symptoms, and in addition suffers from an axillary aneurism of the right side. The tumor is situated under the clavicle and pectoral muscle; it is compressible; pulsation is very distinct; and the aneurismal bruit is clearly heard. Since admission to the Hospital the aneurism has been increasing in size. November 13, at a consultation, it was determined to tie the subclavian in the third stage. The artery was reached without difficulty and a ligature was placed upon it. When the ligature was tightened, the aneurismal thrill and bruit entirely ceased, and in the course of a quarter of an hour the size of the tumor had considerably diminished.

Nothing occurred in the after treatment worthy of especial notice. The ligature came away on the sixteenth day. The tumor diminished considerably, and became firm to the touch. Numbness and loss of strength continued more or less until May 15, 1861, when the patient was discharged cured.

Case 4.—Mr. D., æt. 37, a farmer from Conn., of healthy and temperate habits, stated that four years ago, after recovery from an attack of pneumonia, he discovered a small tumor just below the left clavicle. This tumor gradually grew larger, and he observed that it pulsated, and he could hear a noise in it. Six months ago it began to be painful. He spoke of going to the war, and consulted his physician, by whom he was informed of the seriousness of his disease, and recommended to live a life of quietness, and to avoid all exertion. On the 17th of September, 1861, he shouldered a sack of corn to take it to the mill, and immediately felt that he had hurt himself in the tumor. From this time it has increased rapidly, and become very painful; pains also traverse the arm and hand. Dr. Bostwick now wrote to me, and I visited the patient at his home on the 1st of October.

On examination, I found a pulsating tumor which filled the axilla, and extended under the whole scapula behind, and under the pectoral muscles in front. The scapula was raised, as was also the clavicle. The measurement on the left side, from the centre of the clavicle to the spine of the scapula, was twenty inches. That on the right side, from the same points, was twelve and a half inches.

Oct. 2.—Everything being in readiness, the patient was etherized, and I tied the subclavian artery in its third division. Some little difficulty was experienced in the operation from displacement of the parts, and the artery was found to be very deep. The vein was pushed upwards from under the clavicle.

Nov. 16.—I received a letter from Dr. B., in which he stated that the patient was "up and about." He

omitted to state, however, the period of separation of the ligature.

April 14, 1862.—Mr. D. called upon me, and reported himself in excellent health. The tumor has diminished in size one-half, and is no longer a source of annoyance.

CASE 5.—In which the subclavian was tied in its first portion, together with the common carotid and vertebral arteries. (This case is partially reported in the Transactions of the Pathological Society, in the *American Medical Times*, March 5, 1864.)

H. D., æt. 32, carpenter, had enjoyed good health until August, 1862. At that time he noticed a tumor as large as a walnut, immediately above the centre of the right clavicle. This, he said, came on without any injury or blow that he could remember. It remained of the same size for nine months; but for the last three months it has been gradually enlarging.

I saw the patient in August, 1863, and the diagnosis of aneurism was at once made. The tumor was considerably larger than a walnut, and by pressure upon the axillary plexus was causing much pain and numbness in the hand and arm. For the present, he was advised to return to his home in the country, to take no violent exercise, and to live upon a vegetable diet.

On the 2d of September he returned to the city, and was admitted into the New York Hospital. The tumor now had very much increased in size. It extended from the outer edge of the right sterno-cleido-mastoid backwards for three inches, to the anterior border of the trapezius, and upwards, for about two inches. His nights were sleepless, and there was a very singular change in his circulation. When last seen the pulsations in each wrist were regular, and numbered 76; now the pulsations in the right wrist could hardly be appreciated, and on the left side there was nearly the same condition of things present. The pulsation of the carotid varied from 120 to 130.

A consultation, which was called, resulted in a decision to tie the common carotid near the bifurcation, and secure a good plug, and also the subclavian inside of the scalenus, together with the vertebral artery. It was thought best to tie the vertebral, in order to guard against the accident which occurred in Dr. Rodgers's case of ligature of the left subclavian in 1845.

Operation.—An incision was made from the centre of the interclavicular ligament upwards for two and a half inches. A second, beginning at the same point, and following the upper margin of the clavicle, was extended outwards a distance of four inches. The integument, fasciæ, and platysma were then raised and turned aside. The sterno-mastoid, sterno-hyoid, and sterno-thyroid were then divided as near as possible to the clavicle, and dissected up. The carotid was now seen, somewhat enlarged, and a ligature passed around it without tying, while search was made for the subclavian. After careful dissection a ligature was passed around the subclavian close to the innominata. The carotid was then tied one half inch above its origin. Search was now made for the vertebral, which was found somewhat deeply situated, and it was tied a quarter of an inch from its origin. The subclavian was then tied close to the innominata. The vessels all appeared to be healthy; the wound was closed, and cold water dressing applied. The case progressed exceedingly well until the tenth day, when there was a slight hæmorrhage, which, however, was easily controlled.

On the twelfth day the ligature from the vertebral artery came away.

On the fifteenth day the ligature of the carotid came away. This was followed by a slight hæmorrhage, which, however, had nothing to do with the artery itself.

The ligature of the subclavian came away on the twenty-fourth day.

On the 29th of September there was a slight and easily controlled hæmorrhage.

Oct. 1.—Suppuration from the wound was very free, although nature has done a great deal towards closing the wound, the tissues having gradually broken away under the influence of pressure, and the persulphate of iron which has been used to check the bleeding.

Oct. 7.—Hæmorrhage to the extent of three ounces, and pretty free. In the evening, again, hæmorrhage one ounce. He rallied, however, from all this until the forty-second day after the operation, when hæmorrhage again occurred, and he died.

The autopsy, which was made by Dr. Sands, will be found fully reported in the number of the *American Medical Times* previously referred to. It may be well enough to state, however, that the innominata was found completely filled with a firm coagulum. There was also a plug in the distal end of the carotid, and in the distal end of the vertebral. The distal end of the subclavian did not contain any clot, and water injected into the aorta made its escape from the wound through the open mouth of this artery.

NEW YORK, 37 East 12th Street.

THE MEDICAL USE OF ELECTRICITY.

BY G. M. BEARD, M.D., AND A. D. ROCKWELL, M.D., OF NEW YORK.

No. III.

IN the case of a woman afflicted with syphilitic rheumatism and neuralgic pains of the left shoulder, we were able at first to give only a very temporary relief. The first six applications enabled her to raise her hand to the top and back of the head, which she had not been able to do for a number of months; but she soon relapsed, and was as bad as ever. She seemed inclined to persevere, and we continued to give her applications of the faradaic current, descending and ascending, alternately, over the affected shoulder.

Occasionally, also, we operated over the vital organs. After a protracted treatment of over two months, we succeeded in greatly relieving her neuralgic symptoms. She did not recover the full use of her arm, although she could easily raise it to the top and back of the head. Her appetite, which had been poor, decidedly improved.

Case Fifth.—Mrs. R., of Rochester, a married lady, æt. 38, came to us in August, 1866, complaining of severe and protracted paroxysms of pain in the fourth toe of both feet, that had distressed her for eleven years. Her story was a singular one, but in its essential particulars was typical of some of the cases that we are called upon to treat. She represented that for a long time hardly any week had passed in which she had not suffered pain, that often extended up the leg to the hip; and that her mental emotions—anxiety, terror, depression—at once telegraphed themselves to the diseased nerve and excited pain. Her general health was only fair, and her temperament was decidedly nervous. Sitting too long in over-heated rooms or in crowded assemblies—fatigue, produced by any cause, even the annoyance of listening to a dull sermon, or a sight of a strange clergyman in the pulpit, would make themselves felt in the offending members, and give rise to intense agony. There were no evidences of inflammation of the tissues of either toe, other than soreness of the first joint. Eight general applications of the descending faradaic current were given, but the patient apparently received no benefit.

Her pains still continued at intervals; nor was her general condition improved as much as usual in such cases. Moreover, slight œdematous symptoms appeared. She left us, and as we supposed, entirely discouraged.

Four weeks ago, she came into our office, looking fresh and healthful. She said that for three months after leaving us she had experienced no pain; that her general health also steadily improved; but that a slight attack, a few days previous, brought on by a cold, had warned her of the liability of a recurrence of her old paroxysms, and for that reason she desired an application.

There can be little doubt that she is destined to suffer other attacks at times; for if the theory that such painful symptoms are caused by inflammations within the sheath of the nerve be true, then a paroxysm may be brought on at any time by long-continued exposure to cold.

Anæmia, Dyspepsia, and General Debility.—Our attention was first called to the utility of electricity in dyspepsia, by patients who were treated for other diseases, with which indigestion, in its various phases, was complicated.

Those upon whom general applications were made, reported an increase of appetite, relief of constipation, diminution in the frequency of attacks of sick headache.

Case First.—Mr. S., of Connecticut, came to us, complaining of headache, ringing in the head, vertigo, acidity of the stomach, distress after eating—in short, of all the usual symptoms of dyspepsia. His organization was distressingly nervous. All his movements were characterized by an unusual swiftness and haste. In his conversation, business and pleasure, the world and religion, were strangely mingled.

We half suspected incipient insanity. We told him that the treatment would be protracted, and advised him to receive an application once or twice a week, at least. For the first week or two there was no very marked improvement, although he said he always felt very much exhilarated after each application. After four or five sittings, the change for the better was very decided. Not only were his dyspeptic symptoms relieved, but his general nervousness was diminished.

His appetite was less capricious and exacting. Said he, "Before I tried electricity, I had to eat seven meals a day; now I can get along with only three." His brain seemed to progress with his stomach. His conversation was more subdued and logical. When we last saw him, he was a calmer as well as sturdier man, although not wholly free from dyspeptic symptoms.

In his case, there was no increase of muscular development, which is so often observed after repeated general applications.

Case Second.—Mr. T., a bookseller, aged 31, stated that for a number of years he had suffered from chronic dyspepsia, which had rendered his life miserable. He had lost much in flesh. Although 5 ft. 8 in. in height, his weight was but about one hundred pounds. He complained of regurgitations from the stomach of an intensely sour liquid, and on rising in the morning he was often troubled with pyrosis. Tympanitis was a frequent symptom, and oftentimes the accumulation of gas within the stomach embarrassed the respiration, and disturbed the action of the heart. Treatment was commenced about the middle of October, 1866, and continued for four weeks, the faradaic current being applied three times each week. The daily regurgitations, the tympanitis, and pyrosis, gradually ceased to annoy him; and after the tenth application, he informed us that during the month he had increased in weight some fifteen pounds.

About the beginning of January, 1867, he called upon us, stating that his health was excellent, and that his total increase in weight, since he first commenced treatment by electricity, was some thirty pounds. He said that he did not feel that his digestive organs were as strong as they had been, before he was attacked with dyspepsia, but they had ceased to give him any considerable annoyance.

Case Third.—Mrs. H., a widow lady, aged 32, came to us, Dec. 1st, complaining of a stiffness of the left knee, which had annoyed her for more than fifteen months, to such an extent that at times she was absolutely unable to walk. She was also troubled with an unpleasant cough, and some difficulty of the throat. Her bowels were much constipated, her digestion imperfect, and her circulation languid.

She was exceedingly nervous, and at times her sleep was much disturbed. From the fact that other joints were occasionally affected, we were inclined to the opinion that rheumatism was the cause of the swelling and stiffness of the knee.

General tonic applications were recommended, down the spine, over the stomach, liver, and bowels, and especially over the affected joint. Immediate relief was experienced after the first *séance*. She was able to raise her left foot four inches from the floor, and the pain was greatly soothed. The next day she complained of some soreness, which is very often the case after the first general application. The same treatment was continued for one month, the patient visiting us three or four times a week. We examined her throat with the laryngoscope, and found a slight pharyngitis and laryngitis, that readily yielded to topical applications of nitrate of silver. The improvement was more rapid than we had anticipated. Her appetite became exceedingly keen, the bowels regular, her sleep refreshing, and the color returned to her cheeks. Moreover, the cough, which had caused her much unnecessary alarm, nearly disappeared. The patient was so pleased with the invigorating effects of the applications, that she persisted in the treatment for some time after the knee had ceased to trouble her. A short time ago she fell and injured her knee, causing it to exhibit inflammatory symptoms, that readily yielded to a repetition of the same treatment. Her general condition continued to be excellent. It is probable that she will have recurrences of the affection of the joint.

Amenorrhœa.—Electricity has been used for both suppression and retention of the menses, by several continental physicians, and with excellent results. Dr. Garratt treats such cases continually and successfully.

Dr. Fordyce Barker has reported two or three cases of amenorrhœa successfully treated by electricity, in the New York *Medical Journal*.*

Case First.—In the early part of September, 1866, a young lady of eighteen came into our office and inquired what we could do to cure her disease of the heart. Her speech was only in broken utterances, and her breathing was short and rapid. She was decidedly anæmic, and had been troubled with amenorrhœa for two months. The patient was so hysterical that the first application was given with difficulty. Whenever the strength of the current was much increased, faintness was at once produced. After the first week, however, she could bear a current of ordinary strength without discomfort.

The treatment was continued for one month—the patient visiting us every other day. By that time her apparent cardiac symptoms had disappeared; her breathing was more natural; her cheeks full of color, and her

* Vol. I. p. 188.

step more firm. Her menses returned after the eighth application.

Case Second.—Miss D., aged 25, was sent to us by Dr. James L. Brown, to be treated for suppression of the menses, caused by a sea voyage five months previous. She was stout and vigorous, and complained of no other symptom. According to Dr. Brown's diagnosis, there was no organic uterine disease. We gave her a general application with the descending faradaic current. The next day she said that some blood had appeared. The application was repeated, a strong current passing over the bowels and lower portion of the spine. With that utter disregard for the interests of science that is not uncommon with that class of people, she visited us no more. Two weeks afterwards, one of us met her by chance, and ascertained that she had a healthful flow for two or three days after she left our office.

Case Third.—In the case of a Mrs. L., aged 37, also sent to us by Dr. Brown, we were not as successful; but the case is of interest, as exhibiting the tonic effects of general and persistent applications of the induced current.

For eighteen months she had not seen her courses, although she had been skilfully treated for a long time. Her general health was poor, and she was somewhat anæmic. Her appetite was feeble and capricious, and her rest was much disturbed. She was also annoyed with constipation, and with neuralgic pains in the hip. She was so near the change of life, and had given so little evidence of yielding to her previous treatment, that we gave her but slight encouragement. Six or seven applications with the descending faradaic current were given with good results, so far as her general health was concerned; but her menses did not appear. We then applied the positive electrode against the os, and swept the negative over the lower part of the bowels and spine, and vice versâ, until we became convinced that it was useless to continue the treatment any longer. When she left us, her appetite was good, and her bowels regular; she could sleep soundly, and no longer experienced the neuralgic pains—but there were no indications of a return of her courses.

We believe that merely local applications, however varied and persistent they may be, will give very uncertain results in the treatment of amenorrhœa.

Chorea or St. Vitus's Dance.—This strange and frequent malady we find to yield to repeated tonic applications, in nearly every case, although the treatment must often be quite protracted.

Mary S——, aged 14, first exhibited symptoms of chorea in the right side of the face, and in the right arm, April, 1866. She grew worse slowly, until November, when she came to us for treatment. General tonic applications were made about three times a week. Over the cerebellum, the head was far more than ordinarily sensitive to the current. After two weeks we could discern not the slightest improvement, and all parties concerned apprehended a failure. The treatment was continued a month longer, and with most pleasing results. She had good control over every movement, and her general health was excellent. In all cases, we find that the spasms diminish in proportion to the bettering of the general condition.

The above, both in its results and in its difficulties, is typical of a number of cases that have come under our treatment. To what extent relapses will occur, if at all, time alone can determine.

Rheumatism and Paralysis.—The profession are so familiar with the results of electrical treatment in cases of paralytic and rheumatic affections, that it seems almost superfluous to detail our experience with them. We employ the induced current successfully in all the stages of rheumatism. Where there is active inflammation, the cure is usually more sure and more speedy than in passive chronic states. *Under the careful use of the descending faradaic current, angry joints are soothed, burning pains subside, and the fiery skin is reduced in temperature.* Upon these facts of our experience, we lay special emphasis, because to use electricity in active inflammation is contrary to all the teachings of the past. We have met with the same gratifying results in our applications to recent sprains and acute conjunctivitis. It may here be remarked that we often fail in rheumatic cases, unless we employ general as well as local applications. The ordinary method of passing the current through the affected joints only, usually does some good, but rarely works a cure.

Case First.—C. W. R., aged 25, had been afflicted with subacute articular rheumatism for more than three years. At times he would seem to be almost entirely free from his trouble; but about twice a year, a severe attack would come on, lasting generally from two to three months. In the middle of July, 1866, after several months of comparative ease, the rheumatism again showed itself, and this time, with but little delay, he came to us for treatment.

On the 3d of August, when first seen, his right ankle was so swollen and painful that he could with difficulty ascend the stairs to our office. His left shoulder and hip, together with several of the joints of his toes and fingers, were also somewhat enlarged. Applications were given at first every other day, and then every third day for three weeks, at the end of which time the swelling in all the joints was dissipated, and the accompanying pain entirely relieved. According to his statement, the patient had never experienced a more severe attack, and its duration had invariably been from two to three months. In this instance he suffered but for one month from the beginning of the attack, treatment having been commenced after the lapse of about fifteen days. He promised to report, if he should have a return of his difficulty, but up to this time (February, 1867) we have heard nothing from him.

Case Second.—Miss L. was a sufferer from severe pains in the shoulder, wrists, and many of the joints of the fingers. The right wrist was considerably swollen, together with the second joint of the thumb, third joint of the first finger, and the second joint of the second, third, and fourth fingers of the right hand. Of the left hand, the third joint of the first finger and the second joint of the third finger were enlarged. Some of the joints were of great size, and this state of things had persisted with little change, for over one year. Treatment was commenced, and continued for three weeks. On the arms, hands, and fingers, the ascending faradaic current was used exclusively. Thorough applications were, however, made over the digestive organs, particularly the stomach.

After the first application, the patient expressed herself as entirely relieved of the pain in the shoulder. The second sitting served to dissipate the swelling of the wrists, but as yet no decrease was observed in the size of the joints of the fingers. These, however, began to yield after the fourth application, and rapidly decreased in size until a cure was effected.

Time must decide how long cases like these will remain exempt from their rheumatic symptoms after they have been once dissipated by applications of electricity.

914 Broadway.

PROPOSAL OF A NEW METHOD
FOR FACILITATING
THE OPERATION FOR BADLY UNITED FRACTURES.

By FREDERICK D. LENTE, M.D.,
OF COLD SPRING, N. Y.

Called recently to a long distance from this place to visit, in consultation, a case erroneously represented to me to be a badly united fracture of the bones of the leg, of some eight or nine weeks' standing, with a request to "bring ether and chloroform, and all necessary instruments," and thinking over the means at my disposal for effecting an improvement in the anticipated deformity, without resorting to a severe operation, I concluded, in case of the *callus* being firmly consolidated, to adopt Brainard's method (drilling it in various directions through one puncture of the skin, so as to weaken it; then rupturing by forcible extension combined with lateral pressure and counter-pressure*) when the idea occurred to me to try an improvement of this method in the following manner: To use a drill of very small size for perforating the centre of the callus through a mere puncture in the skin; then to follow this with an instrument which I shall call a *subcutaneous saw*. The teeth only extend, from its rounded point, about one inch, the blade being smaller than the drill. By this arrangement the saw may be worked to a limited, though a sufficient extent to cut through *callus* very rapidly, and yet not to touch the soft parts with the teeth; and may be turned to cut, first in one direction, and then in another, without withdrawing from the puncture. Should there be any important vessel or nerve lying in close proximity to the distal side of the *callus*, which the end of the saw, though blunt, might irritate or wound, it would be unnecessary to perforate its whole thickness; nor would it be necessary to saw through its whole substance on either side, as a portion could be, indeed had better be, ruptured by moderate force.

As it turned out, no operation was required in the case above alluded to; but I have thought that some other surgeon might wish to make a practical application of my idea. I happened to have on hand just the instrument which, with a slight alteration, was requisite; one which I had had fashioned, when a medical student, for making curved sections of the temporal bone for exhibiting the different parts of the auditory apparatus therein contained. It is here delineated somewhat reduced in size.

The advantage of this instrument in certain cases of vicious union of fracture will probably at once occur to the mind of any surgeon who has had to deal with such cases. The treatment advised in the standard works on surgery, in a case where the *callus* cannot be ruptured by a safe degree of force, is the very serious procedure of converting it into a severe compound fracture, by dividing the soft parts more or less extensively, and sometimes removing a portion of the bone. In certain cases this treatment, or even the more serious alternative of amputation, will of course now and then be required; but it is to be hoped and expected that the plan here proposed may very materially diminish the number of such cases. This treatment is, however, not only applicable, it is suggested, to cases of *very firmly consolidated* union, but to such as are usually treated by severe pressure and counter-pressure, alone or combined with forcible extension for a period more or less prolonged; since the latter procedure, even in cases admitting of its successful application, is tedious, troublesome, and painful, and not unattended by danger. The existence of a very considerable overlapping of the fragments would not necessarily be a bar to the adoption of this treatment, since I have known a case treated in the New York Hospital by refracture a year after the accident, where the shortening of the femur amounted to more than three inches, and was reduced to less than one inch by the operation.

The instrument will sometimes be found useful in another and entirely different class of cases. Thus, two weeks ago, I was called to a case of compound fracture of both bones of the leg; the sharp, bevelled extremity of the upper fragment of the *tibia* protruding an inch through a small wound. It was reduced with some difficulty; but three days ago it was found again exposed, in consequence of sloughing of a portion of the integument, and evidently doomed to necrosis. I was anxious to be rid of it; but it was much too thick to be cut off bodily with the bone-forceps, and a chain-saw could not be passed around it and worked without disturbing the wound and the fracture very much. So, with the assistance of my partner, Dr. Barker, who elevated the soft parts slightly with a narrow curved retractor, I let the point of the saw pass under them thus guarded, and gently sawed through the hardest part of the bone, while another assistant held its extremity with a pair of suitable forceps, and then completed the section with one clip of the bone-forceps without materially disturbing the limb, which hung suspended in Smith's "anterior splint," and with very trifling pain to the patient.

It is possible, it is further suggested, that the method might be applied to old cases of *ununited* fracture, when it is expedient to freshen the fragments by removing their smooth and rounded extremities. It could be more effectually and rapidly effected in this manner than by the means usually employed, and through a smaller wound of the soft parts. In fact, the opening in the latter, necessary for the working of this saw in any case, need not be larger than that made by the smallest tenotomy knife, and would probably heal in twenty-four hours.

March 8, 1867.

* Dr. Brainard was accustomed to wait a "specified time" after drilling, to allow the callus to become softened before completing the operation. F. D. L.

The Alumni Association of Bellevue Hospital Medical College held their first regular meeting at Bellevue College, February 28, 1867, and adopted a constitution. They then elected the officers; who are in future, with the exception of the Recording Secretary, to be chosen annually. The following is the list of officers: For President, Dr. W. T. Lusk; Vice-President, Dr. J. U. Southack; Recording Secretary, E. S. Belden; Corresponding Secretary, Dr. L. M. Yale; Treasurer, Dr. H. Raphael; Executive Committee, Drs. L. B. Irish, J. Ferguson, Griffin H. Rockwell, J. B. Done, W. H. Van Wyck, C. A. Leal, W. C. Osteloh, F. A. Castle, W. A. James, B. S. Thompson, J. Cushman, P. R. Cortelyou, C. F. Roberts, and R. A. Vance. Prof. James R. Wood has offered to the association a prize of one hundred dollars, for the best essay on any subject connected with Surgical Pathology or Operative Surgery; to be awarded at the annual meeting in 1869, at which time the said essay is to be read. The Committee to examine the essays, and award the prize, is to consist of Professors W. H. Van Buren, Austin Flint, Sr., and Stephen Smith.

Original Lectures.

SCROFULOSIS AND TUBERCULOSIS.

BEING A LECTURE BEFORE THE CLASS OF

THE JEFFERSON MEDICAL COLLEGE.

SESSION 1866–7.

BY S. H. DICKSON, M.D.,

PROFESSOR OF THEORY AND PRACTICE OF MEDICINE.

PART III.

TUBERCULOSIS differs from scrofulosis in this, that supposing a general constitutional deterioration or cachexia, it has but one manifestation, we know it but one way, and that is by the deposit of a particular matter. It is, as Vogel calls it, a protein-compound consisting of an amorphous stroma (which is at first probably deposited in a fluid state), with some earthy salts, and with a certain amount of fat. There is albumen, as the base, or fibrine, unquestionably. We find it in various conditions, very rarely in the fluid state; rarely in the colloid or jelly-like; yet it is sometimes found so, as is affirmed by Carswell and others. When we first meet with it, generally it is as the grey or miliary tubercle. What is it? Who knows? Microscopists have failed to tell us clearly; the chemists have failed; there is great difference of opinion as to its nature. Addison says it is the white corpuscle of the blood "stagnated and converted;" Virchow says it is "inspissated pus;" if so a blood corpuscle, a pus corpuscle, and a tubercular corpuscle, are the same. You will find if you trace up the various opinions and conclude that concrete pus and tubercle are the same, you have nothing but the corpuscle to constitute this peculiar morbid matter, the very presence of which strikes every one with dread. At first we find it as grey matter; it soon degenerates into the yellow tubercle, distinguished chemically by a greater amount of adipose matter. Is this a degeneracy? If so, it would seem that we do not follow nature when we give the oily diet to a tuberculous patient. Robin doubts whether this grey matter is tubercle; he thinks it can be distinguished from it, and that tubercle is always deposited as the yellow matter. You find this grey matter in many positions in which the yellow is never found, as, for instance, in tubercular meningitis, to which many ascribe the presence of hydrocephalus. These little points which have been considered tubercular are of the grey tubercle, and never degenerate; the yellow mass is never found there. Virchow speaks of tubercle very contemptuously; he says it is a pitiful birth, a very small cell. The tuber never enlarges; the tubercle enlarges by agglutination, only differing from the cancer cell because it is larger. Virchow says, "if you do not know where it comes from, you do not know what it is;" and says that tubercle is nothing but concrete pus; and as the cancer cell differs only in size, you have no difference histologically between a pus corpuscle and a cancer cell.

As we meet with tubercle, it is most frequently found in the lung, and upon mucous surfaces. Carswell contends that it is upon the mucous surface that it is usually deposited. It takes the mould of the part on which it is placed. It must be deposited in a fluid state, but goes on to accumulate in masses. Louis says you will never meet with it elsewhere without finding it in the lung also. Wherever you do meet with tubercle it seems to have a particular tendency to fix itself in one part of that organ. Thus it is much more likely to be found in the apex of the lung than in any other part; so in a particular part of the brain rather than any other; it is found in the ileum rather than in any other part of the intestine. It is found in the cavity of the uterus at times. There is no organ of the body in which tubercle may not be deposited; but wherever found, it has a particular locality in reference to the structure of that organ where it is usually found. This peculiarity has not yet been explained.

The tubercle is usually contained within its own cell-wall, not in a cyst. It is debated whether it contains nuclei or not. All the changes which go on in the tubercle commence in the centre. Virchow speaks of it as a pitiful product. Carswell says it is unorganizable. It has been conveyed by inoculation to a healthy animal, and has there germinated. The highest proof of vitality that I can conceive of physiologically is the germinal power. This looks as if Laennec and Baron were right when they ascribe to it a sort of individuality. We find that a tubercle communicates tuberculosis from a diseased to a healthy animal; therefore it is not unorganized, unorganizable; it possesses its own vitality, which must be of high order.

How does a tubercle change from the centre? This fact was a great obstacle to those who believe it unorganizable. The most important change is softening, which begins the process of death in phthisis. A tubercle itself does not seem to be injurious but by softening. If you turn over Aitken's pages you find a remarkable contradiction; he admits on one page that it is often deposited independent of inflammation; read on a little further and he comes to speak of tuberculosis, and says we have hardly a right to speak of tubercular deposition—it is only a tubercular form of inflammation.

Tubercle is often entirely indolent. On the dissecting table you will meet with cases where you will find tubercle around which there is no change of condition or of the tissue in which it is deposited, inflammatory or otherwise; perhaps a little thickening or hardening, which may be the result of mere pressure; yet it is often deposited under the excitement of inflammation as a result of the hyperæmia which belongs to the history of tuberculosis.

Lebert says that tuberculosis attacks the internal organs; scrofulosis the skin and periosteum. We have attempted to show that scrofula does not occur from any one single cause; that a concurrence of circumstances must act upon the subject, and act slowly, to produce this cachexia. I believe that point may be considered as settled. Dr. McConahey, of Ohio, maintains the old belief that the use of the hog as food is the sole cause of scrofula, and that those only who use the hog in various modes as food are subject to it. I have no doubt that this animal, of all others used as food, is the most frequently diseased. All wild animals become tuberculated in confinement; I will not say scrofulous. I examined a lion who died in one of our menageries. I found tubercle in all the organs of the animal's body. Sauvag s calls the farcy of the horse a scrofula; monkeys in the zoological gardens die of consumption tuberculated. The horse is a very delicate animal when tampered by domestication. All domestic animals become delicate except the cat; this animal seems to retain its tenacity for its nine lives whether wild or tame, and is the only animal domesticated without deterioration of its powers of life. But while we find that scrofula is not very readily manifested primarily on the external surface in those subjects in whom we recognise the affection in the lymphatic glands as separate from tubercle,—while we are clear on this subject, as requiring climate, diet, atmospheric, hygienic, and other influences to produce this cachexia, we know that the separate, modified, or distinguishable

cachexia tuberculosis is producible rapidly and under morbidly favorable circumstances. If typhosis is tuberculosis—but when there is a deposit I suppose it to be tubercular, for we are told you cannot distinguish it from tubercle,—we find in typhus fever, very frequently, sudden tuberculosis. Bell says this is common in Glasgow, and you find it occur occasionally everywhere; both in true typhus, and perhaps more especially in typhoid fever, the patient frequently dies of tuberculosis—of the lung even—when not suspected of having tubercles. How is it produced? By the vitiation, shall we say, of the fluids? of the solids, too, then; how shall we make a distinction between them? The question has been asked concerning many cachexias and morbid diatheses, where do they arise, in the solids or in the fluids? I once thought it a matter of some consequence to determine this point; I now regard the solids and fluids physiologically as the same—the blood is floating flesh. If we believe the doctrine of correlation of forces we must believe that heat is a mere dynamic force, to use a tautology. I am not a believer in this doctrine, yet it has its value and there is a certain amount of truth in it. Take an egg in its natural condition; you say that it is fluid, nothing solid about it but the cell-wall; the yolk itself is composed of cells and is a fluid; but now you expose it to heat—a mode of motion, says Tindall—and what happens? Is there any difference, then? Can you say of an egg, as the source of all peculiarities as well of health as of disease, that it is the fluids or the solids which are concerned? By subtracting heat you cannot bring the egg back again to a state of fluidity, though you can water, which has been frozen solid, by supplying it. Thus we may argue that the fluids and solids are the same; it is a question of distinction without a difference. We do not know where the evil begins; everything is fluid, and everything is solid; the same atom fixed at one moment is flowing at the next. The blood is not a solution of solids in water, it is an interfusion of solids in water. It is impossible, physiologically or pathologically, to distinguish between fluids and solids.

The evil begins unquestionably, as we see, in the very germ itself. Fœtuses are born, dead perhaps, living perhaps, but tuberculated. There are two such instances mentioned in your text-book, of tubercles formed in the lung before birth. The child is often born scrofulous, as we see by the condition of the skin, so that both these forms are transmissible from the earliest periods of existence. The subsequent developments are different and therefore antithetic, and assist in separating them. When we deal with scrofula, everything we see on the surface is of an inflammatory character, modified; on the eye, on the face, little vesicular points containing lymph—I have watched them scores of times. This dries and a little ulcer forms, which heals for the most part readily; as soon as the ulcer ceases, the redness disappears, and everything is right except a little opaque spot. This will happen, sometimes, upon the cornea. You find the Meibomian glands exposed to irritation and inflammation; and scrofulous eyelids are very common; sometimes the resulting thickening will last a whole life, the patient being very susceptible to the formation of styes. The various cutaneous affections are all inflammatory; so are the affections of the glands; and the changes in the glands, notwithstanding Prof. Flint, whose book I so often press upon you as worthy your most careful study, says that the condition of the gland is very similar to the condition of the tuberculated swelling. Far from it; there is no tubercular deposit in the gland; it is a change there, corresponding to that going on in the formation of an abscess, and in the centre there will be formed pus; or in some part of it, after it thickens and hardens, like a common phlegmon, you will find it soften. Pus is formed in that strange way in which blood corpuscles are converted into pus corpuscles; but tubercular deposit does not take place; sometimes it will be laudable pus. Sometimes it breaks down, becomes oily, curdy, etc., but still it is inflammation, and is to be treated as such. You learn to do with it all that is necessary in the case of an abscess; you poultice it, you open it, so that it shall not cause an unsightly scar by opening of itself; but in tuberculosis this does not happen.

Every living thing increases and undergoes changes from the centre. It has been a great puzzle to many pathologists to know why tubercles soften, undergo their change, in the centre first, as a general rule; but so it does in the glands, though it is a different change. What is the change taking place in a tubercle? There are several such changes; one is the softening with which you have much to do in phthisis. This is a very important change; it is always attended, as far as we know, with inflammation around it; it excites inflammation near it, breaks and softens. It undergoes other changes which are contrasted with the softening, in that they tend towards the healing condition. Obsolescence is one; the tubercle seems to lose its normal form. Virchow insists that tubercle, itself, never masses itself; that it is an agglutinated condition; it always consists of grey masses of little tubers, which do not coalesce in their ordinary condition; they are always tubercles, therefore the appropriateness of the diminutive. Beale says that these changes in the centre are a peculiarity of life itself. When the obsolescence commences in the centre it becomes like old cheese, often as hard as horn, and in this state it is only mechanically an irritant for a little time, and becomes afterwards entirely indolent and does no harm. It undergoes another change. An absorption takes place of the animal matters, the albuminous and fatty, etc., leaving the earthy matters, and you have a cretaceous substance left there which is sometimes spit up, and the patient gets well, with a puckering of the lung. If it is not spit out, it is in an indolent condition, and is nothing more than a mechanical irritant. It is the softening of the tubercle that is a specific and dangerous element. Again, osseous matter is sometimes deposited strangely enough. Under what peculiarity of circumstances the tubercle becomes osseous, we do not know; but when it does become so, it is only a mechanical difficulty, and does not do any harm. Now, these changes do not occur in the scrofulous affections. They are marked in their difference in this respect, and thus we separate the two diseases to a certain extent. I acknowledge that they run together to a certain degree. Another writer says that scrofulosis is curable, and tuberculosis incurable. I do not think this is a matter of certainty. Le Grand maintains that in scrofula the blood is impoverished, and the inflammatory element is taken away; on the other hand, that tubercle implies the retention, at least, of that portion of the blood which is liable to inflammation. Ringer and Dr. Parkes have been making some careful experiments with the thermometer, and they maintain that in all cases while tuberculosis is going on, the heat of the body rises above the average rate—rises up to 102° F., perhaps—and this for a length of time. They do not give us any experiments upon the condition of the body while a scrofulous gland is undergoing inflammation. In many of these cases, the inflammation is enough to produce fever, and the thermometer would show the increase then. Sometimes they go on without affecting the constitution with fever. It is certain that when the tubercle begins to soften, this is the fact; hectic fever is fully developed, and the different parts

around the tubercle undergo a decided change. Not so with the scrofulous gland, which does not necessarily inflame the parts about it to any great degree, though there is, of course, some irritation of the parts around. It is important to get rid of scrofula, to understand the nature of the hygienic conditions which favor it, and the hygienic conditions opposed to it.

We do not know entirely the condition of savages, yet I do not believe that they are free altogether from tuberculosis; this can be built up suddenly. I do not know that there is any proof of scrofulous affections attacking the savage, or half-barbarous man, living in a wild state, and in a good climate. Our navigators tell us nothing of scrofula affecting the natives in the cold countries; and in warm climates, the frequent exposure to the open air prevents the occurrence of scrofula pretty effectually. We know less of scrofula in warm climates than in temperate and colder ones; not on account of the temperature, but on account of the housing up and avoiding of fresh air to protect from the cold.

Reports of Hospitals.

LONG ISLAND COLLEGE HOSPITAL.

Clinic of Prof. Austin Flint.

CASES OF HEART DISEASE.

Case I.— *Valvular Lesions: Aortic Direct, and Aortic Regurgitant Murmurs.*

History.—John Schantz, æt. fifty years, a shoemaker. He states that for several years he has experienced deficiency of breath on exercise, and occasional palpitation. Complains of a sense of distress referred to the præcordia, and latterly has suffered lancinating pain in this region, shooting through to the shoulder-blade. Seldom has cough; never had dropsy; pulse is feeble, somewhat irregular, quick, and jerking. Visible pulsations in the carotid arteries are strongly marked. He is notably anæmic; appetite poor; bowels regular. Never had articular rheumatism.

Physical Examination.—The pulmonary organs are normal. The impulse of the apex beat is in the fifth intercostal space, and falls in a vertical line passing through the nipple. Percussion reveals only moderate enlargement of the superficial or deep cardiac regions. On applying the stethoscope over different portions of the heart, two murmurs are discovered, viz. aortic direct, and aortic regurgitant. The latter has its maximum of intensity over the body of the organ, near the nipple. It is feeble, but still appreciable at the base. The former is heard loudest over the base of the heart. It occurs with the first sound, and is propagated into the carotids.

℞. Tinct. Ferri Mur., fl. ʒ i.
Sig. 20 drops three times a day.

Moderate exercise in the open air, and a nutritious diet, were also advised.

Progress of the Case.—March 20, patient has continued to take the medicine for two weeks. He reports that he feels better. The pain has left him, and his appetite and strength are improving. He was advised to continue the same plan of treatment, having reference to his anæmia and general condition.

Comments.—Endocardial murmurs are termed diastolic or systolic, according as they occur during the diastole or systole of the ventricles. Thus the mitral regurgitant and the aortic direct are systolic; the mitral direct and the aortic regurgitant are diastolic. Corresponding murmurs referred to the tricuspid and pulmonic semilunar valves are of extremely rare occurrence. The localization of cardiac murmurs does not involve so great a refinement in the application of the principles of physical exploration as those who have paid no attention to the subject are apt to imagine. Practice only is requisite to enable the auscultator to readily refer them to their proper source. It is only when the normal rhythm of the heart-sounds is greatly disturbed by irregular or excessive action, that much difficulty is experienced.

The points which require attention in the discrimination of murmurs are chiefly three, viz. the situation of the maximum of intensity, the direction in which they are best propagated, and their relation in point of time to the normal heart-sounds.

A murmur occurring with the first sound, heard with its maximum of intensity, at or near the apex of the heart, and best propagated laterally towards the lower angle of the scapula, can be no other than a mitral regurgitant. A murmur heard during the same interval of time, loudest at the base of the heart, and propagated in the direction of the large vessels, must be an aortic direct.

Again, if the murmur be confined to a circumscribed space near the apex, preceding and ending with the first sound, it is mitral direct. And lastly, if the murmur be heard over the body of the organ, occurring with the second sound, it is aortic regurgitant. This murmur has been erroneously stated to have its maximum of intensity over the base of the heart.

By due attention to these points, even when several murmurs coexist, they can generally be distinguished without difficulty.

It would appear that the mitral direct and the aortic regurgitant murmur, by both occurring in the same interval of time, and being heard over the same region of the heart, might occasion confusion; but, practically, these murmurs are as readily distinguished as others. The former is really more closely associated with the first than second sound. It is sometimes called presystolic. It begins feeble, and gradually increases in intensity, until it is finally cut short by the closure of the mitral valve. It also possesses a peculiar vibratory quality which is quite distinctive.

The aortic regurgitant, on the other hand, is more closely associated with the second than the first sound. It begins with its maximum of intensity and gradually dies away. It is often useful, in identifying the first sound, to recollect that it occurs synchronously with the impulse in the carotid artery.

Cardiac murmurs, although interesting as exemplifying the wonderful precision to which the art of physical diagnosis has attained, yet derive their chief practical importance from their connexion with the valvular lesions which they represent. We should never attach too great importance to the presence of a mere cardiac murmur, since neither the intensity nor quality of a murmur affords any criterion of the amount of damage which the valve has sustained. The most serious lesions are often found associated with feeble murmurs, and, *vice versâ*, a trivial lesion, which involves neither obstruction nor regurgitation, not unfrequently gives rise to a loud murmur. Thus a little roughness of the curtains or segments of a valve, caused by a small deposit of lymph in endocarditis, while occasioning but little or no impairment of its functions, may yet be sufficient to produce a very loud murmur. The term "Regurgitant," therefore, used to designate murmurs, is open to objection, as frequently involving a misnomer. Assuming that we possess the means, in any given case, of deciding whether

the lesion has actually occasioned insufficiency of the valve—and this point we may generally determine by characters relating to the pulse, diffusion of the murmur, and other signs—more expressive terms would be, "Aortic Diastolic with Regurgitation;" and so also, "Mitral Systolic with Regurgitation," or "Mitral Systolic without Regurgitation." We may, by means of the stethoscope, directly interrogate the valves in such a manner as to derive information respecting their physical condition, and thereby ascertain to what extent their function is impaired, if at all. This is an important application of auscultation, to which attention has especially been called of late. It consists in comparing the aortic and pulmonic second sounds by listening over the regions where they are respectively heard with their maximum of intensity. These regions are in the second intercostal spaces, near to the sternum, on the right side and on the left. Normally, the aortic second sound has a greater intensity than the pulmonic. Now, the effect of lesions involving obstruction or insufficiency of the valves is, after a time, to weaken the aortic second sound, and thereby render the pulmonic relatively more intense. Whenever, therefore, on comparing the aortic and pulmonic second sounds, we find their normal relation of intensity preserved, though a loud murmur should coëxist, we may yet safely infer that it denotes but a trivial lesion, and that the valve still performs its function well. It thus appears that endocardial murmurs, though interesting and important, as implying the existence, seat, and character of valvular lesions, are yet limited in their significance to these points. As regards the intrinsic nature and extent of these lesions, they give us little or no information. Aortic valvular lesions, as contrasted with mitral, present certain traits. Pain much more frequently accompanies the former. Their pathological phenomena are most apt to be manifested primarily in the heart itself, while those of mitral lesions are manifested primarily in the pulmonary organs.

Finally, as relating to prognosis, aortic lesions, when occasioning great obstruction or regurgitation, by tending directly to induce dilatation and weakening of the left ventricle, involve a greater liability to sudden death.

JEFFERSON MEDICAL COLLEGE,

PHILADELPHIA.

SURGICAL CLINIC OF PROF. GROSS.

SATURDAY, DECEMBER 22, 1866.

Scirrhus of the Mammary Gland, with Atrophy—Removal.—A mammary gland has just been removed from Mrs. S——, æt. 45, well nourished. In the upper part of the tumor there is a cyst which was surrounded, when cut into, with firm, hard, whitish walls. Scirrhus may form the walls of this cyst, for when opened there escapes a brownish, chocolate-colored fluid. There is very little of the glandular structure left in the tumor, it having become atrophied, but there is an immense amount of adipose tissue—much more than I have ever witnessed in proportion to the size of the tumor. The retraction of the nipple is very marked in this case, the existence of which retraction is one of the most diagnostic symptoms in doubtful cases. There was very little hardness and swelling, and the patient's general health is most excellent.

I saw this patient a few months ago at my office, and expressed doubts as to the nature of the case, and gave her strict injunctions to keep her hands and fingers off the organ. Yesterday she returned, and I found the nipple retracted, in a slight degree as yet, but well marked, although there was no considerable induration or enlargement anywhere; and I therefore advised her, as a matter of safety, to submit to the operation which has just been performed.

Sometimes, especially in women far advanced in life, we occasionally meet with a form of scirrhus of the mammary gland, a tumor not larger than the smallest pullet's egg, or an almond in its shell. This is scirrhus of the atrophic variety—scirrhus combined with atrophy of the mammary gland—an uncommon occurrence, and one in which the prognosis is as a general rule rather favorable. The patient may frequently live a number of years without any tendency to ulceration or lymphatic involvement, or constitutional contamination; and if the operation be finally performed, there will be less disposition to a recurrence of the disease at the sutures in the neighborhood of the wound, or in other parts of the body.

The best plan is not to excise the mammary gland when in this condition, but to let it alone. The patient may live for years, and die from some intercurrent disease, without the affection of the mammary gland taking on any diseased action.

In dressing the wound left after the removal of the mammary gland, I prefer long and narrow strips to broad ones, on account of greater facility for drainage. In addition to the strips crossing each other in different directions, we make use of the compress to bring the contiguous surfaces in contact with each other everywhere. The adhesive strips do this to some extent, but not firmly, and therefore we aid them by the application of an oiled compress, not too large, for that would encumber the parts and render them too warm. Attention to this point is a matter of great importance. Then the compress should be confined by a roller bandage passed around the chest. The dressings should be removed at the expiration of the third day, or sooner if there is any considerable discharge. If the dressing remains perfectly sweet, it need not be disturbed for four, five, or six days, according to circumstances.

SATURDAY, DECEMBER 29, 1866.

Chronic Abscess of the Thigh.—Clara B——, æt. 12, has an abscess upon the thigh, which was first noticed eight weeks ago. It began apparently spontaneously, with great pains in the upper portion of the thigh. The patient has also Potts' disease of the spine, a large curvature low down posteriorly. These parts are consolidated; the chasm which formerly existed having been bridged over with callus or new bone.

With regard to the abscess: we have here an affection coming on two months ago, engrafted upon a constitution not very strong, with general health not very good, occurring in a scrofulous state of the system as indicated by the Potts' disease of the spine existing at a former period, but now perfectly well. There is a large swelling upon the outer and upper portion of the right thigh; there is discoloration over a considerable space; also some enlargement of the subcutaneous veins, which are seen swollen and congested; there is very great heat in the swelling—very much greater than the heat of the limb below it, and considerably greater than the temperature of the limb above it; there is, therefore, inflammation. The patient has shooting pains occasionally, but the pain is not sufficient to prevent sleep at night; feels chilly sometimes, and the feet are always cold.

The swelling is not hard; the finger sinks in it very readily, not indenting the parts as in anasarca or œdema, for the moment the finger is removed, the parts resume their former condition. Palpation evinces fluctuation—the presence of a fluid.

The question arises, what is the nature of this fluid? is it blood? is it water? is it pus? If it be blood, its existence would imply the infliction of violence, or the existence of a rupture of some of the blood-vessels of the part, either spontaneously, or as the result of injury or of disease. There has been nothing of this kind in the history of the case; it came on without any assignable cause; therefore we exclude that view from the diagnosis. With regard to its being an accumulation of water; the disease is of two months standing, and there is nothing in the history of the case which would afford reason to believe that there is anything of this kind, which would imply the presence of a cystic tumor, or an accumulation as occasionally happens in the connective cellular tissue beneath the skin, or between the muscles and the skin. Then we come to the consideration, is it pus? It is undoubtedly of that description; the tumor has been growing steadily with all the evidences of inflammation. Then it is an abscess. Is it a phlegmonous, or a chronic strumous abscess? The previous history gives evidence of its being a strumous abscess; the disease is chronic. A phlegmonous abscess is rapid in its formation, and attended with a great deal of pain. The disease is simply a reflection of this peculiar strumous diathesis, which has prevailed probably ever since the birth of the child, to a greater or less extent, displaying itself at about the fourth year of age by Potts' disease of the spine. The abscess, which is quite large, is situated superficially in the subcutaneous cellular tissue; I have no idea that it communicates with the articulation. The child has been becoming lame for the last six or seven months; this right leg was stiff and she could not bend it. It is therefore possible that there may be some complication with hip-joint disease, but the existence of such a condition of things is doubtful. The child has had no rigors, nor night-sweats. This abscess is lined by a pyogenic membrane, formed out of the fibrine or lymph of the blood thrown out by the process of inflammation, in which the pus is contained, by which it is surrounded and circumscribed, by which its diffusion among the surrounding structures is prevented. Such an abscess may exist for many months without awakening any considerable degree of constitutional disturbance or sympathetic derangement, as long as it is permitted to have its own course; but when interfered with, by an opening being made so as to allow of the ingress of the air, then severe constitutional symptoms are excited, sympathetic irritation is provoked, followed by hectic irritation, or hectic fever, as commonly called; in other words, by night-sweats, by great depression of the system at large, by exhaustion, by a sort of typhoid condition of the system, and sometimes by colliquative diarrhœa. When these symptoms prevail, there is great danger with regard to the life of the individual, and it is exactly the same thing which prevails in the latter stages of consumption, in affections of the hip-joint, also in affections of the knee-joint, the larger articulations; the same thing which occurs not unfrequently in scrofulous diseases of the bones, especially the smaller bones, and the articular extremities of the long bones.

The question arises, what should be done in a case of this kind? The matter is making rapid progress, and by its pressure produces in the skin unnatural heat, unnatural discoloration, a congested condition of the blood-vessels of the part, of the veins especially. There is a tendency, therefore, over a considerable surface, to ulceration, which is hastened or promoted by the pressure which the pus itself exercises on the skin; and if the parts are permitted to remain in this condition, the pus will force a vent or opening for itself in a comparatively short period; perhaps within the next ten or twelve days; perhaps sooner. I propose therefore to anticipate this opening, making an incision at the most dependent portion of the abscess, so as to give free vent to the fluid as fast as it is deposited within this pyogenic sac; then, by means of pressure made with a compress and adhesive strips, we shall bring together the opposite surfaces of the abscess, and in this manner diminish its cavity, and, at the same time, guard against the introduction of the air as much as possible. The air itself is comparatively innocuous, but when it is brought in contact with pus in an abscess, it leads to a decomposition of the pus, or putrefaction, and in this way becomes a source of irritation. Whether the pus is absorbed into the system or not, simply by its contact with the pyogenic membrane, or the surface with which it lies in contact, some may get into the blood and poison it; its contact with the affected surface is sufficient to bring about this local and systemic irritation which we call pyæmia. We transfix the wound produced by the puncture with a pin, and then cover it in with adhesive strips. Should the edge unite, it will be very easy to make another puncture in a few days in order to let out some more pus. Immediately after the operation we give the child a full dose (twenty-five drops) of laudanum, which is less likely to produce perspiration than morphia, to prevent undue reaction after the performance of the operation. It is well *always* to anticipate this reaction, and, if possible, to prevent it. A full anodyne will quiet the system, quiet the heat, and conduce to sleep. Then, it will be well to put the patient gradually on the use of quinine and aromatic sulphuric acid, two grains of the alkaloid with twelve drops of the acid, four times in the twenty-four hours. Sulphuric acid is the great remedy in colliquative sweats and hectic irritation.

The pus drawn from this abscess, eighteen ounces in quantity, contains a large quantity of fatty matter, and large peculiar flakes, looking like soft-boiled rice, much like the pus expectorated after cavities have formed in pulmonary consumption; the thinner portions will remain on the surface, and the caseous portion will subside to the bottom, and the supernatant liquid will present a sort of oleaginous appearance. This operation may be repeated in a week or ten days, and finally, when the system has become inured or accustomed to the suffering, the abscess must be opened freely, a tent be inserted in the bottom, so as to give the parts a chance to heal by the granulating process; or a seton may be inserted through the walls and be allowed to remain thirty-six or forty-eight hours, and some irritating fluid, as a weak solution of the tincture of iodine, may be injected; but I prefer to lay open the abscess freely, not immediately, except where it is very superficial, as on the chest, with the view of exciting the granulating process; but in a case like the present it is better to proceed more cautiously. The patient must be provided with a nutritious diet.

Dangers of "Waterfalls."—According to the authority of M. Linderman, a Russian savant, seventy-five per cent. of the false hair used for chignons in Russia, is invested with a parasite to which the name of gregarine is given. This hair is very like other hair in appearance, but on close inspection little dark-brown knots are seen at its free end, and may even be distinguished by the naked eye. These are the parasites. It has been found very difficult to destroy them with any reagents that will not also destroy the hair. The presence of gregarines is doubtless due to the filthy habits of the women who supply the hair to the different markets.

Progress of Medical Science.

POLYPUS OF THE PROSTATIC PORTION OF THE URETHRA.—A case is related in the "*Union Médicale*" of October 6, of a young man who was troubled with his urine, and had seminal emissions. He submitted to cauterization of the prostatic portion of the urethra with Lallemand's porte-caustique, and the surgeon in withdrawing it met with a painful resistance which he supposed to be caused by a mucous fold of the urethra caught in the instrument in sheathing it; but on removing the instrument a urethral polypus accompanied it, and was found to have been the cause of the urinary disturbance.

TEMPERATURE OF THE BODY IN CONVULSIVE DISEASES.—Drs. Charcot and Bouchard state that there is no sensible increase of the general temperature of the body during the clonic contractions of muscles. The augmentation of temperature due to muscular contraction, as in epilepsy, occurs only during the tonic contractions. They assert that in the most marked forms of paralysis agitans, and in chorea, there is no appreciable increase of the animal heat. These opinions are sustained by their physiological essays on cats and rabbits, which animals were thrown into convulsions by injections of sulphate of strychnia, or by the application of electricity. The bulb of a thermometer placed in the rectum of the animal enabled the experimenters to note the variations of the instrument as the tonic convulsions succeeded or preceded the clonic contractions.—*Gazette Médicale of Paris.*

INFLUENCE OF VASO-MOTOR NERVES OVER SECRETION.—M. Brébant, of Reims, has put forward a theory of the relative action of the sympathetic and ordinary nerves, which is different from that of M. Bernard, and which seems plausible enough at first sight. Taking the submaxillary gland as an illustration, he says this organ is provided with two distinct sets of nerves: the chorda tympani, and the filaments of the sympathetic system. The sphincters of the vessels of inosculation obey the chorda tympani, and those of the capillaries obey the sympathetic. If no excito-motor action excites the chorda tympani, the vessels of inosculation remain open, and the blood passing from one set of vessels to the other does not enter the minute capillaries; consequently there is no secretion: the gland remains inactive. If, on the contrary, says M. Brébant, the chorda tympani is called into action, it produces contraction of the sphincters of the inosculating vessels, and these latter being closed, the blood flows on to the ultimate capillaries, and thus secretion takes place.—*Lancet.*

SEQUELÆ OF SURGICAL OPERATIONS.—M. Maisonneuve thinks that of every hundred patients who die after surgical operations at least *ninety-five* are poisoned. This he explains by showing that in most cases of the kind referred to, certain morbid products, the result of the operation, are developed either in the blood or on the surface of the body, and make their way into the system. He formulates his remarks thus:—(1) The blood and other animal fluids, when exposed freely to the air, or in contact with aqueous substances, soon lose their vitality. (2) Once dead, they are liable to putrefy under the influence of heat, moisture, and air. (3) The products of such putrefaction are highly poisonous. (4) It is the same with such secretions as the urine, bile, and intestinal juices. (5) In infiltrating the permeable tissues with which they are in contact, these poisoned liquids give rise to gangrene, erysipelas, &c. (6) These same liquids, either by themselves or mixed with the special products of inflammation they provoke, can, in entering the circulation, alter the blood and disturb important functions. (7) After their expulsion from the general blood-vessels they may remain in the capillaries, the parenchymata, serous tissue, &c., and give rise to abscess, anthrax, &c. (8) The entirety of the disturbances constitutes surgical fevers. To prevent these terrible consequences of operation, M. Maisonneuve suggests the adoption of the subcutaneous method, and the employment of all means of preventing putrefactive process.—*Lancet.*

CLEANING BUILDINGS BY STEAM.—A new process for cleaning the façades of public buildings and dwelling-houses is now being experimented on in Paris. A steam-engine supplies pipes of gutta-percha with a constant stream of the vapor. These are applied to the stone of the brick surface of buildings, one man directing the steam jet and the other using a brush. The building, after the application of this system, looks as clean and new as when erected. A couple of men in three days will thus wash the façade of a hotel at a great economy of time and money over the old mode of cleansing.—*American Artisan.*

BLISTERING is a favorite remedy with many practitioners, and is resorted to for various purposes. Not long ago all internal inflammations were treated by external vesication, perhaps solely from its supposed derivative or substitutive effect. Puerperal inflammation once combated with venesection, mercurialization, and extensive external vesication, is now more successfully treated with anodynes, and simple fomentations. Inflammation of the lungs and pleura, formerly treated by the whole armament of depletion, is now in the best manner controlled by rest, position, and anodynes, the blistering, bleeding, and starvation wholly omitted. Inflammation of the eye, in its various forms, formerly submitted to leeching, blistering, cauterizing, low diet, etc., is not often at the present time subjected to the action of such remedies, but terminates more safely under milder measures. The diseases most eminently requiring, as supposed, the action of these remedies, are now known to recover as rapidly and certainly without them, and thus we are furnished with presumptive evidence, at least, that they are nearly, perhaps wholly incapable of good better, if we could also add of harm, but we are obliged to confess, that if unproductive of good, they are yet potent for evil.—*Dr. Julius F. Miner, Buffalo Med. and Surg. Jour.*

THE URETHRA VIEWED BY A MAGNESIUM LIGHT.—Dr. E. Andrews, in an article upon this subject in the *Chicago Medical Examiner*, says, "Some months ago I had an endoscope constructed after the Parisian plan, and used it with some degree of satisfaction; but there is often a deficiency of light in these instruments, rendering the view unsatisfactory, unless all parts are in perfect order. Seeking to overcome this evil, I one day procured some small magnesium wire, which, when held in the flame of a lamp, burns with a white light, whose brilliancy dazzles like the glare of the sun at noonday. Introducing the endoscope into the urethra of a patient, I caused a friend to insert the wire into the flame of the lamp. The result was to illuminate the urethra magnificently. The mucous membrane, with every little fold or patch of varied color, was as plainly in view as could possibly be desired. It could not have been seen any better had it been dissected and laid in the sunlight. By gradually withdrawing the tube, the whole of the canal may successively be seen

as it collapses across the end of the tube. Seeing the perfection of this illumination, I have ordered a spring and some small wheel-work attached to the lamp, so that the wire may be made to advance into the flame without the help of an assistant. In this way, no doubt, the difficulty of the illumination will be fully overcome, and the urethra can be inspected almost as easily, and quite as perfectly, as the tongue."

TREATMENT OF GONORRHŒA—Mr. Barwell has for years past treated gonorrhœa as a simple non-specific disease, avoiding copaiba, which, by disordering the stomach and causing loss of appetite, depresses the health, and is apt to increase or lengthen the disease. In case of a first attack, in which inflammation runs high, a purge, hot bathing, and an alkaline medicine, either diuretic or aperient, as may be indicated, followed by an injection of sulphate of zinc—two grains to the ounce. Second or subsequent attacks may be treated without such preparation by injection, free action of the bowels being secured, if necessary, by medicine. If the patient apply on the first day of the discharge showing itself, a week may often suffice to check it. More chronic cases may be advantageously treated with tannic acid—three or four grains to the ounce: and, in order that the fluid may remain longer in contact with the mucous membrane, it may be thickened with starch or sugar. Mr. Barwell has not found that orchitis follows the use of injections of the above strength more frequently than it succeeds to gonorrhœa not locally treated; and stricture is certainly a rarer sequela to such treatment than to a clap allowed to run on for weeks or months. The slight but continuous discharge of a gonorrhœa become chronic is often difficult of cure. Turpentine, either Chian turpentine or Canada balsam, with black or Cayenne pepper, is frequently useful. Tincture of steel and tincture of capsicum often avails. As a pepper, cubebs will have a similar effect; but it is not better, and is more clumsy, than the above-named sorts. The most certain and efficacious treatment is by an ointment containing from three to five, and even to ten, grains of nitrate of silver to the ounce of lard. A small bougie smeared thickly with the ointment is passed from half an inch to an inch and a half down the urethra, and left there for half a minute or more; and this should be repeated at least every other day. In general, commencing with the mildest ointment, one need not increase the strength beyond five grains to the ounce. In only one very obstinate case was it used ten grains to the ounce; but the patient got well without a bad symptom.—*Lancet.*

THE INOCULABILITY OF TUBERCLE.—A very interesting communication has been made to the Pathological Society by the President (Mr. Simon, F.R.S.), in reference to the production of tuberculosis by inoculation. Mr. Simon said he had followed up the novel experiments of Continental observers, and had succeeded, by the introduction of the tuberculous matter, in producing tuberculous deposit in several rabbits, some of whom belonging to the same litter on whom this experiment had not been performed were entirely free from any disease of the kind. In the case of rabbits inoculated with matter obtained from other rabbits in whom tuberculosis had been produced, the development of tubercle was much more general through the lungs and the body (and also in greater amount), as though the tubercle had become acclimatized, so to speak, to the system of the rabbits. In one case, that of a doe, the only apparent effect was to cause every fresh litter to be still-born. Mr. Simon observed that his experiments seemed to show that the disease was produced as well when the yellow tubercular deposit was used as when the grey granulation material was employed. Dr. Andrew Clark recounted his own researches on the subject, and suggested that it would be desirable to suspend judgment upon the question in consequence of the startling inferences that would necessarily be drawn if such experiments were accepted as true. He thought that sufficient arguments were at hand to call in question the results of the experiments of Continental observers. In the first place, the deposit in the rabbit was essentially cellular, whereas the grey granulation of tubercle was corpuscular. He had never seen the secondary concomitants in the case of the disease induced artificially in rabbits, such as pneumonia and the like. The condition described as tuberculization might be produced by introducing any aplastic fluid into the system; and the experiments already recorded by different observers seemed in some measure contradictory: some of them producing the artificial tuberculization with yellow, others with grey tuberculous matter.

The specimens of Mr. Simon, handed round, showed to all appearances tubercular matter; and they were referred to a committee for a report. The facts relative to these pathological specimens are of great interest, as the reception given to Mr. Simon's remarks clearly indicated.—*Lancet.*

ELECTROLYTIC TREATMENT OF TUMORS.—At a meeting of the London Medical Society, Dr. Althaus read a paper on the electrolytic treatment of tumors, this consisting in the passing of a continuous current of electricity through the structure to be operated upon from the negative pole of a battery. He exhibited a very ingenious battery, and a variety of instruments to be used in this process, and showed their effects on saline solutions, albumen, and muscle. The diseases best suited for this plan of treatment were tumors such as nævus, bronchocele, hydatids, cancer, etc., aneurisms, varicose veins and piles, serous effusions and strictures, as it caused no bleeding, little or no pain or shock, no sloughing, or other bad effect. He had used it with apparent good effect in cases of bronchocele, scirrhus, and molluscum, but thought it capable of much wider extension. Mr. W. Cooke suggested that as the effects were so local, and as the introduction of the needles into the tumor would always give rise to a certain amount of irritation, the tumor if cancerous might grow faster than it was destroyed. Dr. Handfield Jones had tried it for the removal of a wart, but had found the pain intense. Dr. J. Brown thought the treatment took too much time to be substituted for such a simple operation as that for piles. Dr. Sansom thought the stimulus of the vaso-motory nerves, and the consequent diminution of the quantity of blood supplied to the part, might have as much to do with the lessening of the tumor as any mechanical or chemical action induced by the current.—*Med. Times and Gazette.*

THE BERLIN WARE so much celebrated for its power of withstanding heat, acids, and alkalies, is composed, according to Dingler's *Polytechnic Journal*, of 45 parts kaolin, 37½ alumina, and 16½ felspar. The enamel is composed of 42 parts sand, 33 kaolin, 13 unburnt gypsum, and 12 of the baked body composition above described.—*Scientific Am.*

CHOREA TREATED BY ETHER SPRAY.—A case of obstinate chorea successfully treated by ether spray, has been reported by Dr. Lubelski, in a recent number of the *Gazette Hebdomadaire.* The vapor was thrown upon the sides of the spinal column by means of the double-nozzled apparatus of Richardson.

THE MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

ONE of the medical events of the year will be the meeting of the American Medical Association, which is to be held in Cincinnati, on the 7th, 8th, and 9th of this month. The locality has been happily selected, and from the fact of its being a central one, will no doubt call forth a large attendance of delegates. But we are not to look to this alone as an indication of a full meeting. Last year we had occasion to notice the paucity of Southern members, and to deplore the existence of any supposed political misunderstanding which might account for it. This, if it even did exist, is now, we trust, numbered with the things that were. The civil war is long enough over to heal all the festering sores which party prejudice has given rise to; and we may reasonably expect a considerable accession of members from the South, among whom will be many beloved and respected and too long absented brothers.

We cannot predict that the meeting will be more than an ordinary one, in which the usual number of reports and resolutions will be offered, unless there be a little diversion upon the subject of specialties. This will undoubtedly be brought up, and will be as much if not more talked about than at the last session. But is the Association any better prepared to discuss it than one year ago? Certainly not; and after all, if it were ready and willing to look at it with an unprejudiced view, no good would come of any legislation upon the subject. No well qualified specialist will feel himself called upon to abandon his field of practice, simply because the American Medical Association sees fit to command him so to do; neither will the general practitioners concede that the specialists are orthodox, because a majority vote in favor of them. Specialism is in its youth in this country, and its real merits or demerits have not yet been fully appreciated. If it have any merits they will become apparent after a while, without any special anticipatory or puffing resolutions. The same can be said regarding its shortcomings. A great mistake has been made in agitating the subject too much, and giving it an undue importance. If it were possible for some of the specialists and anti-specialists to hold their peace at the coming meeting, no one would suffer, and all would be benefited by the amount of time gained. We cannot, however, hope for this, and must come prepared to hear the same old arguments, the same pleading for protection of rights, the same call for sympathy with injured innocence, and the same show of eloquence which have characterized other discussions of the sort; and we can assure ourselves in advance, that the result will be the same.

If the Convention of Medical Teachers bring in their report much interest will be added to the meeting. We have no doubt the measures which the professors may recommend will be practicable and sensible; and the Association will have much to base a discussion upon. In this event they will have the subject of medical education presented before them in a tangible form, and may be encouraged to legislate upon it in the hope that such action may accomplish some good. If the convention of teachers agree to come at the question with the right spirit and in the proper way, they may hope for a hearty endorsement of their views by the Association, and a prompt action upon the propositions which they may advance.

An interesting feature in last year's meeting, was the delivery of a lecture before the Association. This was so well received that the committee of arrangements should take the hint, and provide for a repetition of that part of the programme by the selection of some suitable person who could offer remarks upon a subject of interest to all. We would venture to say, that more were benefited by the discourse on nervous affections than by any other topic, not even excepting that of cholera.

The Association will be better prepared to discuss the propriety of quarantine than last year, as many of those who voted against it then have had ample opportunity to change their views. A proper decision of this question involves great interest; and if the subject is brought up at all, it is to be hoped that a calm and deliberate vote be taken, and that the body clears itself of the stigma which still rests upon the action taken last year.

The meetings of the sections, which may be considered as interesting and profitable as any of the Association proper, should be well attended; and in order that more business can be transacted than is usual, each gentleman who proposes to read a paper, especially if the latter is a lengthy one, should be prepared to present only an abstract of the same. In this way two or three articles could be laid before the section in the time which it has ordinarily taken to read one entire. The sessions are necessarily short, and too much time cannot be given to one document to the exclusion of other equally meritorious ones. The entire paper could be handed to the Committee on Publication, the abstract being prepared only for the sake of the discussion it may elicit.

The places of meeting of the sections should be as near together as possible, and within a short distance of the general assembly hall. This would enable more members to be present, and the interest in the meetings would be proportionably promoted. We have no doubt, however, that our brethren of Cincinnati will do all for the delegates which can be done, to make the visit to the Queen of the West as agreeable as we hope it will be profitable.

In our last issue we took occasion to refer to the fact that the religious press, as represented by the *North-Western Christian Advocate*, of Chicago, had opened its columns to the discussion of criminal abortion. The article in question is understood to have been written by the Rev. Arthur Edwards, the associate editor, long and favorably known in the religious world. Since then, *The Congregationalist*, of Boston, in a recent issue, publishes another article bearing upon the same subject, under the caption, "Fashionable Murder." The author, the Rev. Dr. John Todd, of Pittsfield, Mass., from whose "Student's Manual," in our boyhood, we derived many an ambitious impulse, and who will be at once recognised by some of our readers as one of the original thinkers of the day, addresses himself to the task with his usual vigor.

He says very truly, after complimenting the medical profession as a class for their noble stand: "Even now, as I have reason to fear, *all* the profession are not beyond the reach of personal appeal, or an enormous fee; and I do wish that every such a one could see that a fee steeped in blood and crimsoned with shame, cannot bring a blessing to his family." We regret that our limited space forbids more liberal quotations from the article, but cannot refrain from giving the closing paragraphs:

"If it be said that I have in any measure exaggerated the evil and the fashion of the day, I reply, I would not advise any one to challenge further disclosures—else we can show that France with all her atheism, that Paris with all her license, is not so guilty in this respect as is staid New England at the present hour. Facts can be adduced that will make the ears tingle. But we don't want to divulge them; but we do want the womanhood of our day to understand that the thing can be no longer concealed, that commonness or fashion cannot do away with its awful guilt. It is deliberate, cold murder; and if anything short of the murderer's doom shall fall upon the perpetrators of it at the judgment, the reason will be that there has been great ignorance of its guilt.

"I have now done a painful duty, and have done it fearlessly. To the attention of the gentle, tender heart and conscience of woman I commend this subject with earnest prayer."

In this connexion we may state that the late President of the New York Academy read before that body, at its last session, the copy of a bill before the Legislature, which strikes at the root of the evil by making it a misdemeanor, punishable with fine and imprisonment, to circulate infamous publications throughout the State. Thus the agitation of this question of "voluntary abortion," inaugurated by the profession, has already begun to manifest its influence in circles which are more apt than our own to work reform, because gifted with a greater executive power.

Reviews.

THE SCIENCE AND PRACTICE OF MEDICINE. By WILLIAM AITKEN, M.D., Edinburgh; Prof. of Pathology in the Army Medical School; Corresponding Member of the Royal Imperial Society of Physicians of Vienna; of the Society of Medicine and Natural History of Dresden, etc., etc. In 2 volumes. From the fourth London edition; with additions by MEREDITH CLYMER, M.D., late Professor of the Institutes and Practice of Medicine in the University of New York; formerly Consulting Physician to the Philadelphia Hospital, etc. Philadelphia: Lindsay & Blakiston. 1866. 8vo. pp. 955 and 1114.

THE author tells us in his preface that in the compilation of this hand-book he has attempted to give a condensed view of the existing state of the science and practice of medicine. His plan has been carried out to that perfection that the treatise is as complete a one as can be found in any language. Every department of medicine, whether relating to pathology, nosology, diagnosis, or treatment, is most elaborately and thoroughly discussed. One of the most important features of the work is that assigned to the department of medical geography, or the geographical distribution of health and disease. In this section a philosophical study of the distribution of diseases is taken up, particularly in relation to the physical condition of the earth's surface, and to the variations of their types in the different regions of the earth. This important branch, which has lately received so much attention as associated with sanitary science, has, for the first time, been regularly incorporated in a systematic work. The other subjects in the work receive their proportionate amount of attention, and there is everywhere manifest a care on the part of the author to give all the information to his readers which the most extensive research and study are capable of. The editor, Dr. Meredith Clymer, has contributed his share to the work, by many judicious additions to the original text, which makes the work particularly valuable to the American practitioner. Among them may be named articles on the typho-malarial fever, chronic camp dysentery, cholera infantum, aphasia, and the treatment of the diseases of the respiratory organs by atomized fluids. The work, as a whole, now forms a complete cyclopædia of medicine, and commends itself to those practitioners and students who have a desire to perfect their knowledge of our art, and gain much of that information which is crowded out of the smaller text-books.

The publishers deserve credit, not only for the style in which they have got up the work, but for their enterprise in reproducing such a valuable addition to medical literature.

CONTRIBUTIONS TO THE PATHOLOGY, DIAGNOSIS, AND TREATMENT OF ANGULAR CURVATURE OF THE SPINE. By BENJAMIN LEE, M.D. Philadelphia: J. B. Lippincott & Co. 1867. 12mo., pp. 129.

THIS little book is written for the purpose of pointing out the necessity for proper mechanical support in cases

of angular curvature of the spine. The author starts with the proposition that the disease is generally of the nature of a simple inflammation, often the result of external violence, and in order to treat the affection properly, maintains that the vertebræ must be in a state of rest by being relieved from pressure. If this is not done, disastrous results follow, in the shape of caries and deformity. He takes occasion, in the course of his monograph, to cry out against the practice so rife amongst most practitioners, viz. counter-irritation, as not only irrational but cruel, as it oftentimes, if not invariably, increases the existing inflammation, and adds to the discomfort of the patient. The apparatus which he advises is the one known as Dr. Taylor's, which has for its object the unbending of the abnormally curved spine, by the adaptation of an appliance which is curved in the opposite direction, the oblique processes being used as the fulcrum. The principles of treatment are clearly and logically put, and the cases which are detailed conclusively demonstrate their value. It is a very practical and useful little work, and should be read by every practitioner who may be unfortunate enough to hold to the old-fashioned views concerning the pathology and treatment of this very prevalent and heretofore almost incurable disease. Dr. Lee has devoted himself for some years past to the study of mechanical therapeutics, and has done good service to his professional brethren in embodying his views in this neat, useful, not to say attractive, volume.

INJURIES OF THE SPINE, WITH AN ANALYSIS OF NEARLY FOUR HUNDRED CASES. By JOHN ASHHURST, Jr., A.M., M.D., Fellow of the College of Physicians of Philadelphia; Member of the Academy of Natural Sciences at Philadelphia. J. B. Lippincott & Co. London: Trübner & Co. 1867. 12mo, pp. 127.

INJURIES of the spine have not been studied as they should be. This is in part due to the fact that the cases which are subject to such accidents have been confessedly hopeless; and that there has been no incentive to research. Again, the cases are not of very frequent occurrence compared with other surgical troubles more interesting to study, and more amenable to treatment. Dr. Ashhurst, with an industry that deserves the thanks and appreciation of his brethren, has given us a work which will be considered authoritative, and which must necessarily form the basis for all future monographs upon the subject. His cases, nearly four hundred in number, have been collected from every available source, and have been analysed with rare skill and judgment. He has directed his energies principally towards deciding many questionable points in the pathology and treatment of injuries of the spine, and has been enabled to arrive at the following conclusions:—

"1. Injuries of the spine are not nearly so fatal as is generally supposed, and they have been, not unfrequently, completely recovered from. 2. By watching the symptoms and knowing the lesions which they indicate, the patient's progress towards health or death can be pretty accurately foreseen in most cases. 3. Whenever there is reason to believe that one or more vertebræ have been displaced, extension should be employed temporarily, if that be sufficient; if not, continuously. 4. In no case do resection or trephining offer a reasonable prospect of improving the patient's condition, but on the contrary there is reason to fear that they would increase the chances of a fatal termination. 5. Those cases of spinal injury which are not adapted for the employment of extension should be treated in accordance with ordinary rational and physiological principles. 6. No new mode of treatment is entitled to adoption in a class of injuries so serious as this, unless it can be shown by clinical experience that it is at any rate not less successful than the modes commended to us alike by reason and long experience." The appendix is occupied by an elaborate tabulation of 394 cases. Twenty-six of these were cases in which resection of the spine has been performed for traumatic injuries, and but one of all this number was relieved by such treatment. The book is got up in handsome shape, on tinted paper, and tastily bound.

Reports of Societies.

N. Y. PATHOLOGICAL SOCIETY.

STATED MEETING, JANUARY 23, 1867.

DR. H. B. SANDS, PRESIDENT, in the Chair.

RUPTURE OF LIVER:—HYDATIDS.

DR. WOOD exhibited a specimen of rupture of the liver and hydatids of that organ. The patient was found by a policeman lying across the railroad track in Chambers street, and was soon after admitted into Bellevue Hospital in a collapsed state. Death took place at the end of two hours after admission.

On opening the thoracic cavity, a considerable quantity of blood was found in the right pleural sac, and between the oblique muscles of that side of the abdomen, a large amount of blood was effused. Of the existence of this latter lesion there was ample evidence during life in a notable prominence in the right hypochondrium, attended with dulness on percussion. A large quantity of blood was also found in the abdominal cavity. The right lobe of the liver was extensively ruptured, as well as the diaphragm, affording a free communication between the two visceral cavities. The ninth rib was fractured, and the intercostal muscle between that and the rib above was torn. In the track of the laceration several well developed hydatid cysts were discovered.

NECROSIS OF ENTIRE RAMUS OF LOWER JAW.

Dr. POST exhibited a specimen of necrosis of almost the entire ramus of the lower jaw, which he had removed from a little girl eight years old. About eighteen months ago, the patient first complained of toothache, and that side of the jaw became in consequence much swollen. An abscess formed. Two weeks ago she was presented to the clinic of the professor, when on examination of the part denuded bone was discovered. The exposed portion of the necrotic mass was seized with the forceps, and the specimen was extracted entire without much difficulty. A new ramus had already commenced forming.

MESENTERIC HERNIA.

Dr. MASON presented a specimen of mesenteric hernia which was taken from a dissecting-room subject. The sigmoid flexure of the colon and greater portion of descending colon had been forced through an opening in the mesentery, and was actually in a state of gangrene.

Dr. SMITH remarked that he had presented a somewhat similar specimen, in which almost the entire small intestine had become strangulated, and in consequence of the latter condition, the capillaries of the part had ruptured, accounting for the rapid death of the patient.

Dr. POST referred to the case of a child who had died many years ago with symptoms of strangulated hernia. On making the post-mortem examination he found five feet of small intestine, strangulated through an opening

formed by an adventitious band which was attached to the mesentery. The first symptoms which preceded death were those which attended strangulation by a peanut shell, but these were afterwards marked by the abdominal symptoms soon after ushered in. The adventitious band seemed to contain in its centre a piece of the fin of a fish which had previously been swallowed, and after having ulcerated its way through the intestine became inclosed in fibrinous exudation.

Dr. SANDS related the following remarkable instance of hernia. A little more than a year ago, he went a few miles out of town to see a gentleman suffering from the rational signs of hernia. The history was one of original hernia of the right side. The hernia had been a reducible one, but had not descended in several years. The symptoms at the time were: obstinate constipation, vomiting, some tumefaction of the abdomen, together with signs of great prostration. After a careful examination of the case, he felt so confident that no hernia existed that he dismissed from his mind even the probability of such an occurrence. The man died on the same day. On making the autopsy it was found that death was after all caused by a hernia, but by such a one as could not possibly have been recognised during life. The lesion was upon the right side. Only a small segment of the small intestine was constricted, and was occasioned by the gut slipping behind the peritoneal fascia and between it and the rectal muscle, forming there a complete pocket, the constricted portion of which was formed by a band of false membrane. This strangulation was sufficient to obstruct the fæces but not enough to cause gangrene.

He also referred to a second case of masked hernia, which was also diagnosticated only at the autopsy. The patient was a lady, who after being out riding, suddenly died of prostration. In that case there was femoral hernia of the left side, but no external signs of its existence could be ascertained, either by palpation or percussion. The difficulty in making a diagnosis could be accounted for by the existence of two inches of fat over the part.

Dr. WOOD alluded to a case of hernia which had come under his observation, and in which the sac was formed by the sheath of the psoas muscle. The gut was not mortified, although it was evident that the strangulation had existed for some little time. In this connexion he remarked, that his experience led him to believe that in those cases of internal hernia where the mesentery was involved or the intestine entangled with old adhesions, gangrene of the incarcerated tissues did not take place.

Dr. SANDS was of the opinion that the cause of the accident in the first case reported by him, was due to an abuse of the truss.

MENINGEAL APOPLEXY IN NEW-BORN INFANT.

Dr. LEWIS SMITH presented a specimen of meningeal apoplexy in a new-born infant. The mother of the child had symptoms in the latter part of gestation, which weres upposed to threaten uræmic convulsions. She had pretty persistent headache as well as albuminuria. The physicians who were visiting her were contemplating the propriety of inducing premature labor, when the labor pains set in, and a fœtus of eight months was expelled. The child presented by the breech. The first stage lasted about six hours, and passed off in the usual manner without any untoward symptom. The second stage was much shorter, being hastened by manipulation.

The infant at first seemed to be doing well, but after a time attention was directed to its respiration. It became labored and embarrassed, and was decidedly stertorous in character.

On making the post-mortem examination, the abdominal organs were found healthy. The heart also seemed to be in its normal state. The superior and middle portion of the right lung was inflated, with the exception of a dark red portion. The posterior lobes on both sides had apparently not been inflated, were of a still darker red, and were non-crepitant.

The lesion of chief interest was found in the cranial cavity. On removing the cranial bones, we found an effusion of blood extending up upon the vertex so as to cover the two posterior cerebral lobes, over the posterior surface of the brain, and under the cerebellum. In this latter situation a thick clot was discovered, communicating with an opening in the meningeal artery.

Dr. SMITH stated that he had seen a similar condition of things in two other cases. In both, however, the labor was much protracted, in one forceps being used.

ANEURISM OF AORTA.

Dr. NEWMAN presented a specimen of aneurism of the aorta, which was removed from a young man, twenty-seven years of age, who returned home from his office with headache and died almost immediately after, before the arrival of the physician. It seems that the patient had been treated eighteen months ago for epilepsy, but had recovered from his more frequent attacks, being left with a numbness of his left arm. There were no other symptoms noticed during life that would lead to the suspicion of any serious trouble.

The post-mortem was made fourteen hours after death. The pericardium was found filled with liquid blood which had escaped through a small opening in the posterior part of the aorta. The heart was entirely empty. Nothing aside from a turgidity of the cerebral vessels and a blueness of the dura mater was noticed as the result of an examination of the cranial cavity.

Dr. NEWMAN alluded in connexion with his specimen to the preservative power of carbolic acid, which was in the proportion of 3 iss to a pint of water.

Dr. JACOBI was surprised to find that so small an aneurism had ruptured when the arterial coats were so thick, and the atheromatous deposit was only in its first stage.

Dr. POST exhibited a specimen of fibro-celullar tumor the size of a pullet's egg, which he removed three weeks ago from the upper lip of a man in New Jersey. It had developed between the skin and mucous membrane, and was of seven years' standing. Being attached to the mucous membrane, that portion of the mass was removed by an elliptical incision, the whole lip being cut through as in the operation for hare-lip. The tumor was examined microscopically by Dr. W. B. Lewis.

Dr. ROGERS, after asking several questions in regard to Dr. Hamilton's case, which are however noted in the history, stated that the absence of excessive pain was a very remarkable feature. In all those cases which he had read or heard of, the very opposite condition of things existed.

Dr. HAMILTON remarked that such a circumstance formed one of the most interesting points in the history.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

STATED MEETING, APRIL 1, 1867.

DR. SAMUEL T. HUBBARD, PRESIDENT, in the Chair.

THE PRESIDENT announced that the Comitia Minora had voted to grant certificates of membership to Drs. Alphonso D. Rockwell, Governeur Mather Smith, John

C. Peters, Edward Sheil Finlay, John Phillips Payson White, and Wm. W. Strew.

DISEASES OF THE MONTH.

Dr. Dunster, from the Committee on Diseases, reported the total mortality for the four weeks ending March 23, at 1,621, or 98 less than for the previous four weeks. The causes of death were distributed as follows: Zymotic diseases—305; scarlatina still holding the lead, though rather declining; diphtheria slightly increased; croup diminished nearly one-half; typhus and typhoid unchanged. Constitutional diseases, 430—the tubercular continuing to claim special attention, there being 243 deaths from phthisis, 70 from tabes mesenterica, and 45 from hydrocephalus. Local diseases, 642—of which pneumonia gave 124 cases, and bronchitis 28. Developmental diseases, 134. Violence, 49. There was still an immense preponderance of deaths among the young, 468 occurring under one year of age; and nearly one-half the whole number under five years. Thirty-three persons had died above the age of eighty. The diminution of the aggregate mortality was attributed in part to the favorable atmospheric conditions, as shown by the report of the meteorological committee, and in part to the prompt and efficient action of the health authorities in preventing the spread of contagious diseases.

The President announced the death, since the last meeting, of Dr. Alvan Hyde Turner, a member of the Society since 1862.

ALCOHOL: ITS EFFECTS UPON THE PUBLIC HEALTH.

Dr. Wm. F. Thoms read a paper upon "The Effects of the Habitual Use of Alcoholic Liquors on the Public Health." After an historical introduction, he said that the ratio of deaths from alcoholic poisoning in the city of New York is one to every 4,070 of the population per annum. This, at the usual rate of 28 sick to one death, would give to the whole city one sick from the effects of alcohol to every 145 of the population. In the lower wards of the city there is at least one drunkard to every 50 of the population, and the sickness from this cause is very great. In the various dispensaries and missions with which he is connected, at least one-half of all the cases of sickness that come for treatment are caused directly or indirectly by the effects of alcoholic liquors. The ratio of sickness from this cause in the country is 1 in 750. In London the ratio of deaths from this cause is 1 in 12,800, and the sickness rate 1 in 466. The mortality is less in London than in New York, because the liquor chiefly used in the former city is gin, which, acting on the kidneys, produces a less injurious effect than the other alcoholic preparations. The number of deaths in London has risen and fallen according to the facilities granted for manufacturing, vending, and purchasing alcoholic liquors. Whenever the government, to satisfy distillers and venders, opened the floodgates and suffered them to pour out the poison upon the community, then the bills of mortality invariably rose. When the evil became too great to be borne and the government laid on heavy duties, checked importation and hedged in the traffic, then the mortality was lessened. In the whole of England the death-rate from this cause is 1 in 26,000, and the sickness rate 1 in 860, varying according to the facilities for obtaining alcoholic liquors. Their introduction into general use imparted increased virulence to the character of many diseases; and even new diseases began to make their appearance from this source. The consequences of liquor-drinking were so serious in England in 1725 as to cause the College of Physicians to make public representation of them; and in 1750, when the habit was so general, the same body stated they had 14,000 gin cases under their care, most of which baffled all their skill in medicine.

Among the European regiments in India, according to late information, there was, daily, 1 in every 9.8 intemperate men admitted to the hospital, while of the temperate class of soldiers there was only 1 in 27.1. The death-rate for the year 1865, among the same troops, was 1 in 16.4 temperate; 1 in 7.2 intemperate.

Life insurance companies will not issue policies to those whose habits are known to be intemperate; and if it be discovered after death that a policy has been obtained by the concealment of such habits, it is forfeited.

From Neison's "Vital Statistics" it appears that the intemperate have a greatly increased mortality from diseases of the head and of the digestive organs (especially the liver), while they suffer less than others from respiratory diseases. The following table shows the ratio of deaths from these causes to those from all causes in the temperate and the intemperate respectively:

From diseases of the	*Temperate.*	*Intemperate.*
Head,	1 death in 104 deaths.	1 death in 36 deaths.
Digestive organs (esp. liver)	1 " " 160 "	1 " " 42 "
Respiratory organs	1 " " 80 "	1 " " 43 "
From all the classes combined	1 " " 20 "	10 " " 13 "

The mortality of the intemperate at from 21 to 30 years of age is five times that of the temperate; at from 30 to 40, four times.

The following table shows the comparative chances of longevity with temperate and intemperate persons:

A temperate person's chance of living is:	An intemperate person's chance of living is:
At 20, 44 years longer.	At 20, 15 years longer.
At 30, 36 years longer.	At 30, 13 years longer.
At 40, 28 years longer.	At 40, 11 years longer.
At 50, 21 years longer.	At 50, 10 years longer.
At 60, 14 years longer.	At 60, 9 years longer.

The average duration of life after the commencement of the habits of intemperance is, among mechanics and laboring men, 18 years; among shop-keepers and merchants, 17 years; among professional men and gentlemen, 15 years; among females, 14 years.

With reference to the effects of alcohol in cholera, the paper recited that all experience, both in this country and in Europe, has proved that those who have been addicted to drinking alcoholic liquors, have been the greatest sufferers from that epidemic. In confirmation of this statement, a diagram was displayed showing the relation of the number of deaths from cholera and from all causes to the number of liquor-stores, in the several wards of this city, during the last season. From the numerous authorities quoted in support of the position, we give brief extracts. Dr. Sewall, of Washington, while on a visit to the cholera hospitals in this city, in 1832, writes thus: "Of 204 cases of cholera in the Park Hospital, there were only six temperate persons, and they recovered speedily, while 122 of the others, persons of intemperate habits (when he wrote), had died. Similar experiences," adds the Doctor, "meet us in every other hospital." "At Albany," states Dr. Mussey, "during the same season, cholera prevailed for several weeks, attended with a severe mortality; and it is a remarkable fact that, during its whole period, it is not known that more than two individuals out of the 5,000 members of the temperance societies in that city became its victims." Mr. Huber, who saw 2,160 perish in 25 days, in one town in Russia, says: "It is a most remarkable circumstance, that persons given to drinking have been swept away like flies. In Tiflis,

containing 20,000 inhabitants, every drunkard has fallen; all are dead; not one remains."

The Doctor then dwelt at considerable length upon the injurious effects of intoxicating liquors upon persons suffering from fever, quoting from the works of eminent physicians to support his arguments. Not only is this the case in cholera and fever, but in almost every variety of disease that afflicts mankind. In conclusion of this part of the subject, he gave as the results of his observations in regard to the effects of alcoholic liquors on the human system: First, they destroy the healthy relations of the system; second, they diminish and finally destroy the vital powers; third, they act injuriously on the human system in preventing the organs of restoration from performing their functions in a healthy manner; fourth, they prevent the effectual separation of old and useless matter, and also prevent the new matter from possessing that healthy nature essential to proper restoration; fifth, they have a deteriorating influence in respect of the physical energies of the present generation at large.

Some curious computations were then given, by which,—counting a man's time worth one dollar per day, and 313 working days in the year,—it was calculated that the State of New York loses annually, from the habitual use of alcohol, the sum of $16,257,920.

The paper was accepted.

Dr. Chadsey thought it impossible to get a correct return of the deaths from alcohol in this city. With reference to persons of the Roman Catholic faith, a return of their deaths from its use would prevent their burial in consecrated ground; and he believed it customary in such cases to suppress this as a direct or predisposing cause of death.

Dr. John O. Stone, while recognising the value of the paper as presenting matter for careful thought, doubted the accuracy of some of its statistics and the calculations based upon them. Especially in regard to the effects of regular moderate drinking, upon which the gentleman had enlarged, he thought it would be impossible to obtain facts that should be trustworthy. He was surprised, also, at the conclusions drawn from the comparison of the death-rate in the various wards with their number of drinking-houses. Such methods would open the way to grave error. It is true that the liquor-shops are most numerous in the poorer districts, and that these also furnish the heaviest mortality-bills. But here a multitude of causes combine to increase the rate of sickness and death. And it is not even certain that more liquor is consumed here than in the richer and healthier districts. For while the poor frequent the dram-shops, and rarely take much liquor to their cabins, the rich supply themselves in quantity, and have the means of indulgence constantly at hand. He believed that if there was any salvation for the wretched dwellers in our ill-drained, ill-ventilated tenement-houses, it was a glass of whiskey. The great difficulty was, they expended so much money for whiskey, that they had not enough left for food. Put the same persons under better hygienic conditions, and let them drink as much as at present, and they would probably not be harmed by it. We see constantly, among the wealthy, those who use alcohol habitually without injury. He had been surprised at the great longevity of this class in England, where it is well known they are wont to indulge in free drinking. The evils of intoxication were recognised by all, and he only objected to taking a magnified view of them.

Dr. Thoms replied that for his statistics in regard to the longevity of moderate as well as other drinkers, his authority was Neison. In regard to the ratio of deaths to the number of liquor-stores, he had simply given the facts, without attempting to frame a theory.

Dr. Bibbins said that if the gentleman's figures would frighten any one into habits of temperance he should be glad of it; but he could not reconcile them with the statistics of returns from the British custom-houses, lately presented to a committee of the House of Commons having under consideration the subject of taxation for raising revenue. (The tables had been published in the *Tribune*.). From these it appeared that tax imported liquors as you might, it affected scarcely at all the amount consumed. Cost what they would, the people would have them. This was in direct conflict with the statements of the paper just read concerning the fluctuations in the consumption of alcoholic drinks in England, as dependent upon government taxation. Where should we look for reliable figures upon the question, if not to the custom-house records. and the finance committee of the House of Commons? He would have the Society, as a scientific body, pause before committing itself to conclusions opposed by such authority.

Dr. Peaslee could not harmonize Dr. Bibbins's statement with any principle of political economy. He could easily see how a heavy duty upon spirits might not diminish the revenue, for the rich would still consume as much as before; but that it should not diminish the consumption he could not help doubting, for the poor would be inevitably deprived of their wonted amount. He continued, that at this day, when the war had so greatly increased the use of stimulants; when chemists were assuming, but without a particle of physiological proof, that alcohol could take the place of food, by checking waste of tissue; and when learned theologians were ranging themselves upon the same side, he thought it required a good deal of moral courage to take a stand on the ground of temperance. He was disposed to accept the argument of the paper as essentially sound, and its conclusions as generally true, and not to cavil at any slight errors in its details. His extensive observation had taught him that to both young and old the excessive use of ardent spirits was only harmful. The question of their moderate use was more troublesome; but, according to his experience, a young man of twenty who drinks moderately to-day, will drink excessively twenty or thirty years hence; though if the habit of habitual drinking be not formed until the age of forty-five or fifty, it may very likely be continued in moderation to the close of life. He would not interfere with any man's private practices; but thought it the duty of physicians, in their professional capacity, to avoid carelessly inducing or fostering habits of intemperance in the young.

Dr. Bibbins responded that, if he mistook not, the committee above named had gone into calculations to show how the poor man, by economizing in other ways, managed still to get his usual allowance of liquor in spite of the government duty.

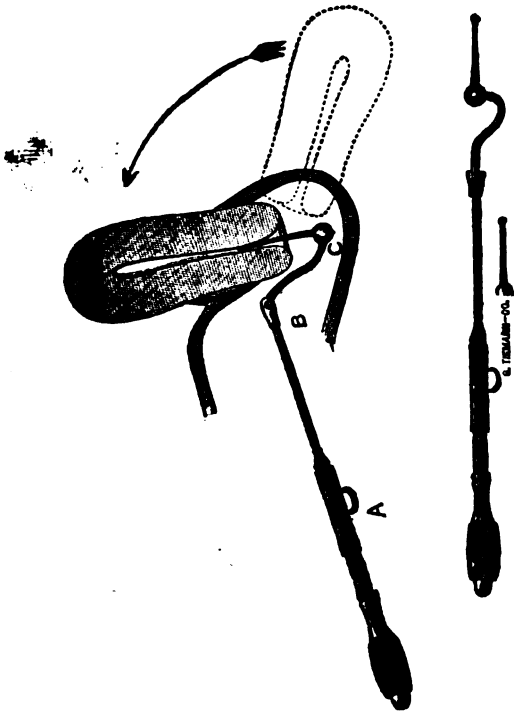
The Extravagance of Allowing Bodies to Decay.—Some of the French utilitarianists propose to put the corpses which are now allowed to rot and waste away in our graveyards, to some more useful purposes, viz.—that of making an illuminating gas. They estimate that a medium-sized adult, by a process of combustion in retorts, is capable of making an amount of gas valued at about eight francs, and large sized corpses in proportion. Verily we live in a practical age.

A Case of Longevity.—Jacob Near, of Webster, Monroe county, N. Y., died on the 28th ult., aged 110 years. He retained, until about a month ago, to a remarkable degree, his intellectual faculties.

New Instruments.

EMMET'S MODIFICATION OF SIMS'S UTERINE ELEVATOR.

Some years ago, Dr. Sims published in the *American Journal of the Medical Sciences*, Philadelphia, an account of a uterine elevator devised by him. It was an ingenious instrument, and replaced a retroverted uterus with great facility; but it was impossible in most cases to withdraw it from the uterine canal, without again retroverting the organ to a great extent. Dr. Emmet has lately modified the instrument with a view of overcoming this difficulty. The patient is placed on the left side (or better, on the knees and elbows if the vagina is small), and Sims's speculum introduced as far as an ordinary vaginal examination. In the latter position, if the operator is without an assistant, he can readily hold the speculum in the left hand and use the elevator with the right, for atmospheric pressure will fully dilate the vagina if the clothing of the patient has been previously loosened about the waist. The stem portion of the instrument is forced into the uterine canal, and by gentle pressure backwards into the *cul-de-sac*, the fundus is lifted into place or anteverted at pleasure. From the ring on the slide at A, a stilet



passes through the instrument beyond the joint at B. By drawing the slide back, the joint B is freed, and on making pressure upwards and backwards against the base of the bladder in front of the uterus, the organ is prevented from turning over again, while at the same time the stem is pushed out of the canal. This instrument has an advantage in the fact that the only point of pressure made is at the os by the bulb C, without the risk of lacerating the lining membrane of the canal as when the sound is used, or any other instrument lifting the organ by its extremities alone. The intra-uterine portion should be of several lengths, and the one used ought always to be about half an inch shorter than the canal. It is screwed into the bulb at C, and being made of copper, it can be bent in conformity to the curve of the canal, if a flexure exists. The instrument has also the advantage that with its use adhesions can be readily detected, with a perfect appreciation on the part of the operator as to the actual amount of force he is exerting.

Correspondence.

FOUR CHILDREN AT ONE BIRTH,

AVERAGING FIVE POUNDS EACH; ALL LIVING AND WELL, AND NURSING THE MOTHER.

To the Editor of the Medical Record.

Sir—Some few weeks ago, the following letter was received from a graduate of the New York University, dated Taylor's Turn-Out, S. C., March 7, requesting any remarks which I might think proper to make, in reference to the interesting case which he details. Accordingly, after reading the case, I thought it of sufficient importance to the readers of your journal to give it in full, as presented by Dr. Faust. I have also taken the liberty of adding my comments upon the same.

I am, sir, very truly,
Gunning S. Bedford, M.D.

Graham's Turn-Out, S. C.,
March 7, 1867.

Prof. G. S. Bedford, 66 Fifth Avenue, New York:

My Dear Doctor:—I have just visited a lady who has been delivered of four healthy male children at one birth. One of the children was born on the 26th of last February, at 11 o'clock A.M., the other three were born on the following day (the 27th), between the hours of 6 and 8 o'clock A.M. There was but one placenta, which was square; cord attached to each corner. The mother is just 25 years of age, and is doing well. All the children nurse the mother, and will average 5 lbs. each in weight.

Thinking, perhaps, that you had not seen such a case recently, and especially where all the children were living and doing well, I deemed it my duty, as an old student of yours, to inform you of the fact, as obstetrics was always your favorite branch. Please let me know what you think of such cases, and how often they occur.

I remain, yours very truly,
C. J. Faust, M.D.

Reply.

66 Fifth Avenue, New York,
March 20th, 1867.

My Dear Doctor:—Your very kind letter of 7th instant I received with much interest. The case of quadruple birth which you describe is, indeed, a remarkable one. You ask me "what I think of such cases, and how often they occur?" Well, I tell you very frankly, that *four* children at one birth, and all "living, and doing well," may be regarded as among the extremely rare phenomena of the lying-in room. I myself have never met with an instance of such fecundity—the richest reproductive result in my practice being once, an example of triplets, two of the infants, with the mother, surviving; the third was still-born. It has been my fortune to bring 33 twins into the world, one of which cases I will briefly mention, as illustrating the fact that the procreation of twins seems to be peculiar to certain individuals and families. Some years ago I attended a lady in child-bed with twins. This lady I confined three times successively with twins. She married a

German gentleman. Her husband was a twin, and his aunt on the maternal side I delivered twice consecutively of two children at each birth.

It would seem that a twin pregnancy occurs in the varying proportion of one in sixty to one in ninety-five cases. Madame La Chapelle records, that in 37,441 births there were 36,992 single deliveries, 444 instances of twins, and but five cases of triplets; and it is an interesting fact that in 108,000 births in the Hotel Dieu, and Maternité of Paris, from the years 1761 to 1826, *there was not one example of quadruple gestation.* In 129,172 deliveries in the lying-in-hospital of Dublin, there were 2,062 cases of twins; 29 of triplets; and but *one instance of a quadruple birth.* Haller (Physiologia, 929), observes, "*non raro femina geminos fœtus parit; rarius paulo tres, neque unquam supra quinque.*

Among British practitioners, in 257,935 births, according to Dr. Churchill, there were 343 cases of twins, or about 1 in 75, and 43 cases of triplets, or 1 in 5,561‡; among the French, in 39,409, there were 336 cases of twins, or 1 in 108, and 67 triplets, or 1 in 6,568; among the Germans, in 369,080, there were 4,239 cases of twins, or 1 in 87, and 38 of triplets, or 1 in 9,765. Taking the whole, we have 666,424 cases, and 8,006 of twins, or 1 in 83, and 87 cases of triplets, or 1 in 7,443.

The following is presented as the rate of mortality: In 1,298 cases of twins (*i.e.* 2,696 children), 636 were lost, or about 1 in 4; and of 12 instances of triplets (*i.e.* 36 children), 11 were lost, or 1 in 3. The mortality to the mother in twin cases has been computed as 1 in 20.

The general rule is that, in plural pregnancy, each fœtus possesses its own membranes and placenta; and, in this particular, it simulates a single gestation, with the exception that sometimes there will be an inosculation of blood-vessels between the different placentæ. On the other hand, it will occasionally, though rarely, happen that there is but one after-birth for the two children; and it has been suggested by Dr. Tyler Smith, that, in these latter instances, the one ovule has contained two yelks, and two germinal vesicles, as is sometimes observed in the case of birds—one egg with a double yelk producing two individuals. The fœtuses in plural pregnancy are usually smaller than when there is but one child *in utero*, and there is, also, a strong predisposition to premature delivery. When there are more than two, the expulsion is still more apt to be premature, and the children rarely survive beyond a short time. It must, however, be admitted that there are well authenticated exceptional examples of the reverse of this latter rule. Dr. Collins cites, within his own knowledge, two instances of *triplets* having arrived at the full period of utero-gestation, and were reared healthy children.

In the great majority of cases in twin-births, statistics show that the second child is delivered, by the resources of nature alone, from fifteen to thirty minutes after the birth of the first. In 212 instances recorded by Dr. Collins, in which the interval is accurately marked, in 38, it was five minutes; in 29, ten minutes; in 48, fifteen minutes; in 23, twenty minutes; in 30, half an hour; in 5, three-quarters of an hour; in 16, one hour; in 8, two hours; in 3, three hours; in 2, six hours; in 1, seven hours; in 1, eight hours; in 1, ten hours; in 1, twenty-four hours.*

In plural pregnancy, it will occasionally happen that one fœtus is healthy, and perfectly developed, while the other bears evidences of an early arrest in its growth, and may be either living or dead. This fact is very satisfactory proof that the lives of the two children are quite independent one of the other.* Again, both children may be fully developed, and alive, but one much larger than the other. Cases, such as I have just mentioned, may very naturally give rise to the idea of *super-fœtation*, and have been attempted to be explained by some writers exclusively upon this hypothesis; but *super-fœtation*, in my judgment, is not at all necessary for the elucidation of the phenomena—they may exist independently of any such influence. For example: this inequality may be due either to some original defect in one placenta or funis, or in one of the fœtuses; or it may result from compression exercised in utero by one child on the other. There can be no doubt of the occasional operation of either of these influences.

A plural pregnancy does not necessarily imply that the labor will not be natural; on the contrary, nature, unless there should be some complication, such as malposition of the fœtuses, will be adequate to accomplish the delivery, through her own unaided resources. The labor, however, as a general rule, will be more protracted, because the uterus, having been subjected to a greater degree of distension, loses in proportion its contractile tonicity, and therefore a longer period is needed for the achievement of the process. And, also, when there is more than one fœtus in utero, the organ cannot concentrate its power as in a single gestation.

The following table, exhibiting presentations of the fœtus in 808 labors with twin children, has been constructed by Prof. Simpson† from the returns of twin-births, as observed in the Dublin and Edinburgh Lying-in Hospitals, and among the patients of the London Maternal Charity:

Reporter.	Total number of Cases.	Number of Head Presentations.	Number of Pelvic Presentations.	Number of Transverse Presentations.
Clarke	126	78	58	..
Collins	449	309	133	7
Hardy and McClintock	190	122	62	6
Ramsbotham	772	532	221	19
Simpson	80	23	7	..
Reid	48	25	22	1
Total	1,615	1,084	498	33
Proportions among twin children		67 in 100	1 in 3	1 in 49‡
Proportions among all births		96 in 100	1 in 81	1 in 224

And now, my dear Doctor, I must close this letter, trusting that it will not be altogether without interest to you. You certainly have accomplished something to be proud of; and I am much pleased that you have added to your little State of South Carolina *four males.*

Believe me to be, most truly yours,

GUNNING S. BEDFORD, M.D.

C. J. FAUST, M.D.

DEATH FROM CHLOROFORM.—A stableman recently died under the influence of chloroform at Saint Mary's Hospital, London. It was administered to facilitate the reduction of dislocation of the thumb.

* Dr. Merriman cites the following case, reported in the *Medical and Physical Journal* for April, 1811, vol. xxv., p. 311. In an instance of twins, the second child was retained for fourteen days after the birth of the first, and the writer remarks that another example had come to his knowledge in which six weeks had elapsed between the expulsion of the twins.—*Merriman on Difficult Parturition.*

* There is no difficulty in accumulating proof of the independence of the two fœtal lives; but the following is certainly a most interesting demonstration of the fact: A pregnant woman was attacked with small-pox, and recovered. She was soon afterwards delivered of twins, the one having received the small-pox in utero, the other not. The case has been reported in the *Journal de Médecine*, edited by Vandermerde.

† Simpson's Obstetric Works, Vol. II., p. 183.

‡ The same tendency to malpresentation also exists in the case of triplets.

TURKISH AND RUSSIAN BATHS.

To the Editor of the Medical Record.

Sir—In these days, when the laws of hygiene are beginning to receive the attention which they deserve, and when their capabilities for diminishing the number and severity of cases of preventable disease are recognised facts, an appeal for the more widely extended use of the only thorough methods of bathing may contribute to the general good.

I advocate the Turkish and Russian baths for those who have no organic or functional diseases to contraindicate their use.

Many physicians are personally familiar with their benefits; many more recommend them in special cases, and approve of their use by those desirous of making a trial of them. But very many know nothing personally of the subject, and hesitate to recommend them, even to healthy persons interested in these baths from curiosity, or for other reasons. Others are influenced by the reports made by patients who have bathed once or twice, and perhaps then imperfectly or injudiciously.

The whole question is yet in the germ of practical utility; but my convictions and my personal experience leave no doubt in my mind of its inherent vitality, and of its ultimate development into another of our national institutions.

The American people display tendencies to dyspeptic conditions; to sluggish skins, prematurely yellow and wrinkled. They are distinguished for their inordinate mental activity, and for the display of an energy in their various occupations which leads them to sacrifice repose, and many hygienic influences, more appreciated in other countries. We inhabit a country with a dry climate influencing most markedly, the evaporations from the skin, and stimulating us to activity. We suffer from the most marked varieties of temperature. We swelter in the summer, and we shiver in the winter. The ethereal mildness of the balmy spring is received by us on the authority of the English poets, and there remains only the glory of our American autumn as a subject of just national climatic pride and congratulation.

All unfavorable influences of climate and national habits combine to suggest the more extended use of the Turkish and Russian baths as a national need; and surely, if slowly, will their hygienic, their soothing, their invigorating influences, commend themselves to our overworked, harassed, and sedentary population.

The American people have purged themselves too long and too often of their "peccant humors" through the bowels. Some emunctory must be opened for our relief; some safety-valve must be contrived for our high-pressure lives; and the intestinal mucous tract has been spurred and forced to perform much of that duty which nature has assigned to the healthy skin.

Is it probable that the frequenters of the Roman baths would have displayed as many post-mortem evidences of renal disease as the great unwashed and sedentary populations of our times? Do we not all force the skin to renewed activity when its yoke-fellow, the kidney, is struggling with disease? Is it not certain that a more thorough and systematic attention to the functions of the skin would prevent many of the diseased conditions of the kidney, so widely spread, that healthy kidneys are rarely met with in autopsies and dissecting-rooms?

Many cases of dyspepsia are susceptible of relief in this way. That these baths facilitate digestion was known of old, and the manner in which they were used for the relief of gormandizers has been made one of the topics of Juvenal's satire. For the relief of rheumatic pains, and as a prophylaxis of rheumatism, there can be no question as to their value. They are better worth than drugs and ointments for many cutaneous diseases. For psoriasis—an opprobrium medicorum—they fulfil the chief indication. The cure of scabies can be hastened by their use, and the risks of tegumentary irritation from the prolonged use of sulphur obviated.

The dark ages were the dirty ages; and with all the development of learning, the wonderful contrivances of printing, postage, and the telegraph, for disseminating and transmitting information; with all the luxuries of dress and home-comforts that mark the civilization of our day; with the expenditures for water supply, and the priceless treasures of our Croton, we are not as clean in our persons now as the old Romans were.

Urquhart, and others, are enthusiastic regarding the applicability of these baths to the cure of tuberculosis; and when one remembers the benefits claimed for these patients, when they pass hours in the sugar-boiling houses on the plantations, it is evident that if any remedial agents were to be found there, the chief must have been heat and moisture.

These baths should be attached to our hospitals, where the existing necessities for large boilers would permit their introduction at a moderate outlay. They should be afforded at a low rate to the packed masses of our tenement-house population.

Cleanliness is next to godliness; and cleanliness can be attained so thoroughly by no other method, as those well know who have taken these baths often enough to have their scarf-skin peeled off, and witness the difference in the rapidity and amount of their perspiration, after the skin has attained to something like a condition of health and freedom in its action. Sir Francis Head reports a Frenchman to have said, after taking the baths at Schlangenbad, "On y devient amoureux de soi-même." At least, one may learn to entertain a proper respect and appreciation for his own skin after these baths have instructed him in its capabilities.

Try them for yourselves, all those who have healthy hearts and sound arteries; but try them frequently enough to know by experience their capabilities for improving your health and adding to the comfort of your life. And though you avoid the *gravida sus* of Juvenal, be sure not to neglect to take a lunch before you go. For my own part, I prefer the baths of Dr. Gutman, in Fourth street, between Lafayette place and Fourth avenue, where they can be taken in combination, and where one can pass directly from the enjoyment of the Turkish to that of the Russian bath. "But let every one be persuaded in his own mind."

Yours respectfully,

Geo. T. Elliot, Jr.

12 West Twenty-ninth street.

PUBIC VERSION IN UTERO—THE WOMAN PLACED ON HER KNEES AND CHEST.

To the Editor of the Medical Record.

In an article, published in the Medical Record, August 15, 1866, I remarked that pubic version, in my opinion, could be performed much easier were the woman placed on her knees and chest than by the usual method. I do not refer now to the operation by external manipulation, but only to one where the hand is required to be introduced into the uterine cavity.

Since the publication of that article I have attended three cases of confinement, wherein pubic version was required, and could not be performed by external manipulation in consequence of the bodies of the children being impacted, and have done the operation according to the above plan with eminent success.

Case I.—Was a Mrs. N——, twenty-eight years of

age, in her fourth confinement. When I reached her bed-side I ascertained that she had been in labor several hours, and that her pains had been very strong. I examined her, and found the umbilical cord presenting, prolapsed about twelve inches, cold and feebly pulsating; also the body of the child lying transversely, considerably impacted. I placed the woman in the position above described; administered chloroform; returned the cord by Dr. T. G. Thomas's method, and without withdrawing my hand, or changing the woman's position, seized the foot, and turned and delivered the child in a few moments' time, successfully, alive and uninjured.

Case II.—A Mrs. D——, aged thirty-five, in her eighth confinement. This case was similar to that of Mrs. N——, excepting the funis was not prolapsed; the side of the child presenting. I arranged her in the same position, and operated in the same manner, without administering chloroform, with like success. Anæsthesia was not resorted to in consequence of her preference to suffer.

Case III.—A Mrs. B——, in her fifth confinement, aged thirty. In this case the shoulder was presenting, and so impacted that it was difficult to distinguish it from a breech-presentation. On being satisfied that it was not breech, I placed her in the position required by the method, administered chloroform, and performed the operation with the same success as related in the other cases. Mother and child doing well as the above.

The position of the women in these three instances I am thoroughly convinced rendered operations very easy, which otherwise would have been very difficult.

The advantages gained over the usual method by thus operating are obvious to any practical obstetrician.

The first is, the relaxation of vaginal sphincter and walls; the second, the gravitation of uterine contents relieving impaction; the third, the retaining of the amniotic fluid during the operation; the fourth, the hand and arm may be introduced into the uterine cavity more nearly in a line of the axis of the superior strait, the cervix and perineum being yielding.

Alex. Hadden, M.D.

Obituary.

CASPAR WISTAR, M.D.,

OF PHILADELPHIA.

The death of this excellent man will be a source of deep and unalloyed regret to all who knew him, for his qualities of mind and heart were such as secured for him the love and respect not only of a large family circle, but also of a very extensive general acquaintance. Indeed, no one could approach him without being favorably impressed by his frank, open manners, and his kind, earnest, genial, and sympathizing disposition. The son of the late venerable Thomas Wistar, and the nephew of the eminent anatomist and surgeon whose name he bore, he naturally inclined to the adoption of a profession which had been so signally illustrated in his family; and accordingly, after the decease of his distinguished relation, he entered the office of the late Joseph Parrish, under whose instructions and those of his associate, Dr. Wood, he prepared himself for the degree of Doctor of Medicine, which was conferred on him in the year 1824. Immediately after his graduation in the medical department of the University of Pennsylvania, he was elected to the office of Resident Physician of the Pennsylvania Hospital; where for the space of two years, he enjoyed advantages for the acquisition of practical medical knowledge such as at that time were to be found nowhere else in our country. Thus qualified for the successful pursuit of his profession, possessing excellent natural endowments, having the certain support of a numerous connexion, the patronage of a wealthy and estimable body of Christians—which then bore a much greater relation in proportion to the population of the city than it now does, though it has in no degree declined from its former influence and respectability—as well as the prestige of a beloved and celebrated name, he might have confidently anticipated a lucrative practice, and the attainment of the highest medical honors and position. The path of professional life, rugged and difficult to others, had been made smooth and easy to him; but whether owing to increasing domestic responsibilities, aversion to the steady, laborious, and exclusive application which is imperatively required to reach a foremost place in medicine, as indeed in all other branches of knowledge, an unwillingness longer to subject a nervous and impetuous temperament to the harassing toils and mental disquietudes inseparable from the life of a physician, or to some other cause unknown to the writer, he soon began to relax his exertions; and after a few years of successful practice, during which he abundantly demonstrated how much more he could have accomplished, he retired from the field, and devoted himself henceforth almost exclusively to the duties of private life, and the promotion of objects of general benevolence and utility. It was in occupations such as these that he appeared in all the beauty and attractiveness of his character. He was always ready to take a part in every enterprise having for its object the alleviation of the miseries and the cultivation of the charities of human life; and many of our public institutions are greatly indebted to him for his active interest and fostering care. The Philadelphia Dispensary especially owes more to him than perhaps to any other person; for throughout the long period of forty years, during which he held the positions of Secretary and President of that admirable charity, its management, of necessity, devolved chiefly upon him; he continued to watch over its welfare with unflagging zeal to the day of his death; and its past usefulness and present prosperity bear testimony to the wise economy and prudence with which its affairs have been administered. The limited space to which this notice is restricted would hardly suffice for the bare enumeration of a tithe of what he effected in almost every department of philanthropic effort. He was a prominent member of the Society of Friends, and with the active benevolence for which that body of Christians is so honorably distinguished, his whole life was devoted to the promotion, in some way, of the welfare of others. A large share of his attention was directed to the improvement, in every mode, of the colored population of the city; and for several years he acted as physician to the Home for Colored Children. His sympathies were ever most deeply moved by fallen man in his most helpless and degraded state; and hence the lively solicitude he evinced for the well-being of the inmates of our prisons, houses of refuge, and other reformatory institutions, in the direction of which he bore an important and conspicuous part. The subject of slavery early engrossed his thoughts; and while his voice was ever heard in indignant condemnation of that barbarous system, his feeling heart and energetic mind were constantly employed in the furtherance of measures for its adoption. To this end he thought, spoke, and wrote with unwearied diligence. As a means of extending his usefulness, and influencing the minds of others beyond the sphere of his personal acquaintance, he assisted at one period in the editorial supervision of

"The Friend," a weekly publication belonging to his Society, and was at all times a frequent and valued contributor to its columns. He was, of course, opposed to the war—in which, however, one of his numerous family, General Isaac J. Wistar, who was badly wounded in the battle in which the lamented Colonel Baker fell, bore a prominent share—but he foresaw at least one good result of the murderous and unnatural strife, in the overthrow of African bondage. His nature was ardent, his perceptions quick, and his acute and ready mind possessed the faculty of fixing almost intuitively on the strong points of any subject submitted to its consideration. His friendships and attachments were strong and unwavering; his address warm and cordial; his conversation interesting and instructive, abounding in anecdote and illustration; he was fond of humor, prompt in repartee, and was a person whom it was always a happiness to meet, and from whose presence one rarely departed without pleasure and improvement. Such, in very brief and imperfect outline, is the character of Dr. Wistar, as it appeared to your correspondent; but it would be incomplete indeed, if it failed to convey the impression that he was an humble and consistent follower of the Divine Redeemer. The true Christian was regarded by our departed friend as the highest style of man; and though conscious of his own infirmities and imperfections, he labored earnestly for the attainment of such excellence. Orthodox in his belief, and reverent in his deportment, he faithfully endeavored to order his daily walk in accordance with that of his great Exemplar, and to bring every impulse of a somewhat excitable temperament into subjection to His precepts. This was more particularly remarkable towards the close of his life; when, impressed with the conviction that the end was approaching, his disposition and manner became singularly childlike and affectionate, calling forth the love and admiration of all around him. He died at his residence in Philadelphia, on the 4th of April, 1867, after a short illness, of serous apoplexy, in the 66th year of his age; meeting the approach of death with the calmness and resignation which characterized his life, and with humble confidence in the merits of his Saviour.

Life will take a darker hue from his departure; but the remembrance of his beaming smile, his hearty welcome, his words of hope and encouragement, his unconquerable resolution, his love of right and scorn of wrong, and his undoubting faith in the final triumph of good over evil, remain to cheer and comfort us during the remainder of our pilgrimage, and to allure us onward and upward along the path which he trod.

All, all are gone; but mid the gloom
A bright and cheering ray is shed,
And memory, bending o'er his tomb,
In certain faith bewails her dead.

L.

PHILADELPHIA, April 17, 1867.

OBSTETRICS THE SCIENCE AND THE ART. By CHARLES D. MEIGS, M.D., late Professor of Obstetrics, Jefferson Medical College. Fifth Edition. Philadelphia: H. C. Lea, 1867.

Medical News and Items.

DR. I. RAY, the well known psychologist, has retired on account of ill health from the superintendency of the Buller Hospital for the Insane at Providence. Dr. John W. Sawyer is his successor.

A NEEDLE IN THE PERICARDIUM, CAUSING DEATH BY HÆMORRHAGE.—A woman, aged forty, was recently admitted and died rapidly with symptoms of fainting, and on examination after death the pericardium was found full of blood which had escaped from wounds caused by a needle. The needle was probably swallowed and eventually worked its way from the œsophagus, in which it probably at first lodged on its way to its final destination.

THE NEW YORK QUARANTINE BILL.—The new Quarantine bill recently passed the Senate, provides that the proposed buildings for the detention of passengers coming in infected vessels but not actually sick, shall be built on the West Bank; but in case it becomes necessary to use a temporary site until the buildings are erected, Barren Island may be used. It also provides that the boarding station of the Health Officer shall be on the west end of Coney Island, and no infected vessel shall be permitted to anchor in Gravesend Bay. One hundred thousand dollars are appropriated for these purposes.

CHOLERA is reported to have broken out at Port Glasgow and Jersey.

REGISTERING NEW-BORN CHILDREN IN FRANCE.—A long-standing regulation in France requires each father or mother to take their children, within three days of their birth, to the Town-hall, and there show them to the registrar. There has been of late considerable discussion in the various French papers concerning the absurdity of the practice. Many children are said to have lost their lives by a compliance with the regulation; especially has this been proved to be the case with those little ones who have been thus carried out in inclement weather and during the severe winter months.

Delegates to American Medical Association from New York Pathological Society.—Drs. Ellsworth Eliot, W. B. Bibbins, E. Krackowizer, A. E. M. Purdy, W. Parker, L. A. Sayre, W. H. Draper, H. B. Sands, A. C. Post, R. F. Weir, S. Rogers, T. C. Finnell, and George F. Shrady.

M. Follin, the distinguished editor of the "*Arch. Gén. de Médecine*," was recently elected member of the Academy of Medicine, subject to the approval of the Emperor. The candidates were M.M. Legouest, Demarquay, A. Guérin, Giraldès, and Verneuil.

Prof. John Goodsir, of the University of Edinburgh, died March 6, at Wardie.

A School for Vivisection.—There is about to be established at Paris a special department of the School of Medicine for the study of practical physiology. What a pity it is that we cannot follow the example, if for no other reason than to supply the President of the Society for the Prevention of Cruelty to Animals some more material for sensational correspondence in the public prints.

The International Medical Congress at Paris will meet on the 16th of August next, and remain in session two weeks.

Super-heated Steam.—A company has been organized in this city for the purpose of introducing Carvalho's patent for super-heating steam. The apparatus is capable of supplying pure, dry steam, of any required temperature. The value of this agent, as a disinfectant, has been so well established by the experiments of Dr. Bell, of Brooklyn, that any means to perfect its application deserve a thorough trial.

Prevention of Purulent Resorption by Ergotine.—Dr. Labat, of Bordeaux, claims that the administration of ergotine in eight doses of five or six grammes daily, for eight or ten days, is attended with very beneficial results in preventing purulent infection.

Amblyopia produced by Smoking.—M. Viardin has reported three cases of amblyopia produced by smoking.

Medical Club of London.—The medical club so long talked of in London has at length been fairly established, and numbers nearly six hundred members.

Physical Culture.—A gymnasium establishment upon a capital stock of $25,000, in shares of $50 each, is talked of in this city, in which every branch of physical culture shall be taught.

A Suggestive Fact.—Damascus, the oldest city in the world, contains 84,000 people. Leavenworth, Kansas, though founded only twelve years ago, has nearly 25,000 inhabitants.

Forced Medical Attendance.—The physicians in Peru are compelled to attend any one who may call on them, at any hour day or night, and in case of refusal are liable to a fine of fifty dollars. An unjust as well as unnecessary measure.

New York Hospital and Bloomingdale Asylum.—From the annual report of the Governors of the Society of the New York Hospital and the Asylum for the reception of the insane at Bloomingdale, it appears that the whole number of patients treated in the New York Hospital during the year 1866 was 2,645. The number of patients in the hospital on the 31st of December, 1865, was 243, and there were admitted during the year 1866, 2,402. The number cured was 1,536; relieved, 475; discharged at request, 68; discharged as improper objects, 23; eloped or discharged as disorderly, 32; died, 283; total, 2,412. Remaining 31st December, 1866, 233, making a grand total of 2,646. There were 95 inquests held at the hospital during the year, of which 10 were in cases of railroad accident.

The number of patients in the Bloomingdale Asylum on the 31st day of December, 1865, was 171, and there were admitted during the year 132, making a total of 303. Of these, 66 were discharged recovered; 33 improved; 12 not improved; 24 died, and 168 remained on the 31st of December, 1866.

The receipts of both institutions, during 1866, amounted to $209,697.44; the expenses to $198,111.94. On the 31st of January, 1865, the indebtedness was $96,450.50, against $84,872, at the same date in 1866.

The rate of board for seamen entitled to the benefit of the United States Hospital fund, has been raised from $6 to $7 per week; the rate for other patients is $6 per week for males, and $5 for females—much less than the actual cost of each patient to the Institution.

N. Y. State Inebriate Asylum.—The trustees of the State Inebriate Asylum, at Binghampton, N. Y., have secured the services of Albert Day, M.D., as superintendent. He was the originator and successful manager of the Washington Home, of Boston, for the treatment and cure of inebriates. They hope to open the institution for the reception of patients about the 1st of May next.

Managers of the Hudson River State Hospital for the Insane.—The following managers have been duly appointed by the Legislature:—Abiah W. Palmer, of Amenia; William Kelly, of Rhinebeck; Dr. Cornelius R. Agnew, of New York city; Dr. A. Cooke Hull, of Brooklyn; Amasa J. Parker, of Albany; Dr. Edward L. Beadle, of Poughkeepsie; George Clarke, of Newburgh; Joseph Howland, of Fishkill; and John P. H. Tallman, of Poughkeepsie.

Peculiarities of Chinese Practice.—The physician approaches the sick-room with courtesy and politeness, and having ascertained the nature of the disease of his patient, proceeds to prepare his prescription. Their prescriptions generally are vast compounds; they go on the supposition, very common with other practitioners, that it is best to give several remedies together, so that one or another of them will hit the case. Sometimes they compound as many as fifty to eighty ingredients, and stew them all together and then administer. They hardly ever prescribe less than fifteen or twenty simple medicines. The physician is not so much a prescriber as a seller of medicines. He tells his customers what he thinks is best for them, or their friends; but it is very frequently the case that they make the selection. For instance, he may make up a prescription of ten or thirty remedies to be compounded, when the question will arise, how much is this to cost? The physician makes as low an estimate as possible, and replies. The patient, or friend, may think it is too high, that it can't be afforded; and one article and another is thrown out, to reduce the cost—often the articles most valuable to the patient. In some cases they cannot agree on a prescription, or its price, and the patient deliberately gives himself to die rather than pay the price demanded.—Dr. Wiley, *Cinn. Lancet and Observer*.

Dr. Joseph Ember, of Vienna, one of the lecturers in the University, gives popular lectures on "The Ear, and its Proper Care," in the hall of the Imperial Royal Academy of Sciences, in Vienna, to which ladies and gentlemen are admitted free of charge. This would hardly do in New York.

Cholera is appearing in Berlin, although in a sporadic form; yet showing epidemic tendencies.

American Medical Association.

EIGHTEENTH ANNUAL MEETING, CINN., O.

TUESDAY, MAY 7, 1867.

FIRST DAY.

THE Association convened at 11 o'clock, in Hopkins's Music Hall, and was called to order by the President, DR. HENRY F. ASKEW, of Delaware. After a prayer by Rev. H. M. Storrs, D.D., of Cincinnati, Dr. John A. Murphy, as Chairman of the Committee of Arrangements, welcomed the delegates in a brief address; after which he announced the places of meeting of the different "Sections."

DR. MURPHY also announced the time and places of the various entertainments and receptions.

After the calling of the roll of delegates by the Secretary, the President delivered his inaugural address, a copy of which was requested for publication.

REPORTS OF COMMITTEES.

The Reports of Committees were next called for, and disposed of as below designated.

On Quarantine, Dr. Wilson Jewell, Pennsylvania, Chairman. Not present; subject dropped. On Ligature of Subclavian Artery, Dr. Willard Parker, of New York, Chairman. Postponed for the present. On Progress of Medical Science, Dr. Jerome C. Smith, New York, Chairman. No report ready; Committee discharged. On the Comparative Value of Life in City and Country, Dr. Edward Jarvis, Massachusetts, Chairman. Postponed for the present. Drainage and Sewerage of Cities, etc., Dr. Wilson Jewell, Pennsylvania, Chairman. Absent in Europe; Committee discharged. On the Use of Plaster-of-Paris in Surgery, Dr. James L. Little, N. Y., Chairman. Report referred to the Section on Surgery. On Instruction in Medical Colleges, Dr. Nathan S. Davis, Ill., Chairman. Made special order for Wednesday morning at 10 o'clock. The report on Medical Education took a similar course. On Rank of Medical Men in the Army, Dr. D. H. Storer, Mass., Chairman.

Dr. D. H. STORER stated, that owing to illness during a portion of the time allotted him to give the subject requisite attention, he was unable to report; that one member had been absent for some time, and another had assured him that it was inexpedient at present to urge further reforms. Report received and Committee discontinued.

RANK OF MEDICAL MEN IN THE NAVY.

Dr. W. M. WOOD, U. S. N., Chairman, reported through Dr. Ninian Pinkney, U. S. N. He contended that while men of the medical profession were everywhere recognised as the equals of those in other professions, in the navy they were degraded below the military, inferior in age, in experience and rank. He said: "Our service is overgrown with usages which sprang up in the earlier and ruder ages of naval life, and still cling to it with a power and tenacity which almost defy modern enlightenment, progress, and even law. It is probable that the national authorities which organized the existing rank of medical officers intended to confer a more substantial fact than the usages of shipboard life have permitted. Among the usages of the service is that which limits an officer's rights and comforts to the apartments in which he messes, even though his rank actually entitles him to higher privileges and greater comforts than belong to those of an inferior rank who make up the majority of the inmates of that apartment. The steerage is the most humble of those apartments, and is the dwelling-place of the very young, or those of no responsibility. The ward-room gathers in it most of the commissioned and some warrant officers, and was originally occupied by none of higher rank than lieutenant. All its usages and government are still conformed to the scale of that grade.

"Now, make a medical officer in name an Admiral, and leave him to be ward-room officer, and the title becomes ridiculous. It is sunk below the usages and restrictions originally designed for those of junior years and inferior rank.

"There is only one mess which is superior to these restrictions, and that is the mess or messes of the commanding officers, and their associates, who may range in rank from a Lieutenant-Commander to an Admiral. Sometimes there are one, sometimes two of those messes. This is very properly left to the will of the Commander-in-Chief, who may choose that he and his Captains may have one or separate establishments. The Assistant Surgeon enters the service with the rank of 'Master.' That this title may not be misunderstood, it may be necessary to explain that it is the lowest rank in the ward-room. For the incumbent is in modern times generally a graduate of the Naval Academy, awaiting his promotion to lieutenancy. Like the 'Master,' the Assistant-Surgeon at once becomes a member of the ward-room mess, and unless the number of partitioned off sleeping-berths contained in the ward-room are occupied by his seniors, he may have the good fortune to occupy one of those that are dimly lighted by an air port, six inches in diameter. This space is so restricted, and the separation from the common apartments is so slight, that words in an ordinary voice in another become common property."

After further presenting the discriminations against medical men in regard to shipboard accommodations, the Doctor said:

"The general law is, that no officer shares in prize money unless his name be borne upon the books of the vessel making the captures, and the Admiral or Commander-in-Chief has a percentage on all prizes made. The Fleet-Surgeon, as a member of the Commander-in-Chief's staff, must be with him in the flag-ship, and as a rule at the post of greatest risk, responsibility, and hazard; consequently he is not likely to have his name borne upon the books of the subordinate vessels making captures, and yet no share of prize-money is allowed him."

The report suggests the following as the remedy for these evils:

1. After they have reached the rank of Commander, or are filling the position of Fleet Surgeon, let them be by right, as they often have been by courtesy, members of the cabin mess. If the mess of the Commander-in-Chief be too exalted a social position for the members of your profession who are filling the important position of Fleet-Surgeon, then let them be members by right of the mess of the Commander of the ship and the Fleet-Captain.

2. An equitable arrangement of prize-money, most important in principle, your Committee hope to see effected. It will, however, require future legislation.

In European countries, the Doctor said, more liberal regulations prevail in regard to naval surgeons than in democratic America.

The late Admiral Foote, so justly distinguished for his large medical liberality, advocated the highest rank for naval medical officers. An Admiral among the most distinguished in the service, has authorized it to be officially said, that he thought the Fleet-Surgeon

should, in our service, as in the French, be a member of the Commander-in-Chief's staff and family. We regard it as opposed to the public interests of the service, which can never be sacrificed to gross indignity without detriment.

Dr. John C. Hupp, of Wheeling, W. Va., offered the following:

Resolved, That the able, practical, and eloquent report just read by Commodore Pinkney, in behalf of medical officers of the navy, be referred to the Committee on Publication, with instructions that it be published. Carried.

Dr. Pinkney then offered the following:

Resolved, That a special committee of five members be appointed by the President, to present this subject before the President of the United States and the Secretary of the Navy, and urge the adoption of the changes proposed. Carried.

Dr. Post, of New York, moved that the same committee be instructed to memorialize Congress on the subject of awarding prize money to medical naval officers. Carried.

The Committee on Insanity, Dr. Isaac Ray, of R. I., Chairman, made no response.

Dr. H. R. Storer, of Mass., opposed the motion to drop the subject, and commented upon the exclusiveness of Insane Asylum Superintendents. He said that the Committee evidently did not, in accordance with their policy, intend to report, and alluded to their spirit as manifested in Dr. Ray's printed statements, that none but experts should testify in the courts regarding matters affecting the sanity of the individual. He suggested, therefore, that this Committee be discharged and a new one created.

The subject was, on motion, postponed for further consideration.

The Committee on American Medical Necrology, Dr. C. C. Cox, Md., Chairman, reported the performance of its duties, but owing to the length of the document, the reading was for the present deferred.

The following Committees, not being present, were discontinued:

On the Causes of Epidemics, Dr. Thomas Antisell, D. C., Chairman. On Compulsory Vaccination, Dr. A. N. Bell, N. Y., Chairman. On Leakage of Gas-Pipes, Dr. J. C. Draper, N. Y., Chairman. On Alcohol and its Relations to Man, Dr. J. R. W. Dunbar, Md., Chairman.

The Committee on the Various Surgical Operations for the Relief of Defective Vision, Dr. M. A. Pallen, Mo., Chairman, had no report. Dr. Pallen's request to be excused from further service on the Committee was granted.

The following Committees, having made no response, were on motion also discontinued.

On Local Anæsthesia, Dr. E. Krackowizer, N. Y., Chairman. On the Influence upon Vision of the Abnormal Conditions of the Muscular Apparatus of the Eye, Dr. H. D. Noyes, N. Y., Chairman. On the Comparative Merits of the Different Operations for the Extraction of Vesical Calculi, Dr. B. I. Raphael, N. Y., Chairman. On the Therapeutics of Inhalation, Dr. J. Solis Cohen, Pa., Chairman.

The following Committees were represented as likely to report, and passed for the present:

On the Deleterious Articles used in Dentistry, Dr. Augustus Mason, Mass., Chairman. On Medical Ethics, Dr. Worthington Hooker, Conn., Chairman.

Of the Committees "On the Climatology and Epidemics of the several States," the reports of Drs. Alfred C. Garrett, of Massachusetts, and R. C. Hamil, of Illinois, being the only ones ready, were referred to the Section on Meteorology, Medical Topography, and Epidemic Diseases.

The Reports of the Treasurer and of the Publication Committee were then submitted.

The recommendation of the Publication Committee that the payment of money for prize essays be abolished, and that in lieu thereof a certificate with a hundred printed copies of the essay be furnished the author, was debated as a motion, and deferred for further deliberation on the morrow.

The following papers were read by title and disposed of as below designated.

"On the Causes of Cholera." By Dr. N. S. Davis, of Illinois. Referred to Section on Meteorology, Medical Topography, and Epidemic Diseases.

"On a New Medium for the Preservation of Anatomical and Pathological Specimens." By Dr. Clapham. Referred to Section on Anatomy and Physiology.

"On the Action of Belladonna in Diseases of the Cornea." By Dr. Joseph S. Hildreth, of Chicago. Referred to Section on Surgery.

"A Bibliography and Observations on the Present Condition of Aural Medicine and Surgery." By Dr. Lawrence Turnbull, of Philadelphia. Referred to Section on Surgery.

"An Abstract of the Report on the Therapeutics of Inhalations." Referred to Section on Practical Medicine and Obstetrics.

"Observations on the Application of Rhinoscopy in Diseases of the Ear." By Dr. Lawrence Turnbull. Referred to Section on Surgery.

"Clinical Thermometry in Diphtheria." By Dr. Joseph G. Richardson. Referred to Section on Practical Medicine and Obstetrics.

"On Extra-Uterine Fœtation." By Dr. Stephen Rogers, of New York. Referred to Section on Practical Medicine and Obstetrics.

"On the Treatment of Diseases by Atomized Medicinal Substances." By Dr. I. Field, of Iowa. Referred to same Section.

The hour for the meeting of the various Sections was fixed at 3 P.M.

The Meeting then adjourned to meet on Wednesday at 9 A.M.

Wednesday, May 8, 1867.

Second Day.

Dr. Henry F. Askew, President, in the Chair.

The Association met pursuant to adjournment. The following were announced members of the Association by invitation:

Drs. J. Taylor Bradford, Augusta, Kentucky. John P. Phister, Maysville, Kentucky. Wm. L. Atkins, Geo. H. Whiting, A. B. Duke, M. L. Forsythe, Paul Rankin, of Kentucky. M. W. Junkins, Galen Hart, E. P. Harrison, of Ohio. D. R. Greenly, Meadville, Pennsylvania. Fred. Wolf, Concord, Maryland. Eugene B. Harrison, Napoleon, Ohio. B. F. Hart, Marietta, Ohio.

Dr. Atkinson moved that a recess of five minutes be granted to enable the delegates to make their appointments to the Committee on Nominations. Carried.

The time having expired, the Secretary announced the Nominating Committee:

For Vermont, J. N. Styles; Mass., H. R. Storer; R. I., Otis Bullock; Conn., B. H. Catlin; N. Y., Ellsworth Eliot; N J., Samuel S. Clarke; Penn., John L. Atlee; Del., H. F. Askew; Md., J. J. Cockrill; W. Va., J. C. Hupp; Ohio, R. McIlvaine; Ky., D. W. Yarnell; Indiana, J. S. Bobbs; Ill., H. A. Johnson; Mich., A. B. Palmer; Iowa, J. C. Blackburn; Mo., B. F. Shu-

mard; Texas, Hurd; D. C., Johnson Eliot; U. S. N., Ninian Pinkney; U. S. A., J. J. Woodward; Wisconsin, N. Dalton; Kansas, John Parsons; California, T. M. Logan; Tenn., T. A. Atchison.

A communication from Prof. Alden March was then read, in which he announced for transmittal to the custody of its proper officer, an album containing the photographs of the Presidents of the Association, from its organization up to the present period. He also declared his intention to add the portraits of future Presidents.

The gift was accepted with thanks.

Dr. March made a few pertinent remarks in return.

Dr. Cox read the report of the delegation to the Foreign Medical Associations, giving an interesting resumé of the proceedings of the British Medical Association, which met in Chester, England, August, 1866.

Report received and referred for publication to the appropriate Committee.

DELEGATES TO THE INTERNATIONAL MEDICAL CONGRESS.

The President then appointed as delegates to the International Medical Congress, Drs. B. F. Barker, J. E. Tyler, and T. C. Brinsmade.

Dr. Atlee moved that the Nominating Committee be instructed to suggest additional names. Carried.

Dr. H. R. Storer rose to disclaim any intention of personality in the remarks made by him the day previous. As he had learned that Dr. Ray, of Rhode Island, intended to read the report of his Committee before the Association, he moved that he be made a member by invitation, and be requested to read his paper at 9 o'clock to-morrow morning.

Dr. Hibbard objected to departing from the rule of referring such papers to appropriate sections, as it would establish a precedent that might consume valuable time of the Association hereafter.

Dr. Walker, of Mass., in a few remarks defended the superintendents of Asylums for the Insane. He claimed that no discourtesy to the Association was intended by those gentlemen. He explained that the reason why they did not unite with this organization was, that their duties and interests as hospital superintendents were different from those of ordinary physicians.

Dr. Gross hoped the report of Dr. Ray would not be referred, but be treated with the courtesy of a hearing in open session.

Dr. H. R. Storer again disclaimed any intention to give offence. He had endeavored to satisfy Dr. Walker of this, but he did not succeed.

The report of Dr. Ray was then made the special order for Thursday, at 9 A.M.

The Committee on nominations were instructed to meet in the Reception Room.

Dr. Atkinson proposed that the committee called for by Dr. Pinkney's resolution consist as follows: Drs. N. S. Davis, Ills.; J. M. Toner, D. C.; S. D. Gross, Pa.; J. J. Cockerill, Md.; H. F. Askew, Del. Carried.

The report of the Committee on Medical Education then came up pursuant to a previous resolution making it a special order.

Dr. Gross, as Chairman of the Committee on Medical Education, presented the report of the same, which was on motion referred to the Committee of Publication.

Dr. Stille followed with a summary of the proceedings of the Convention of Medical Teachers.

Dr. Davis, as Chairman of the Committee on Medical Instruction, then submitted his report. Referred to Committee of Publication.

Dr. Hughes took the chair during the temporary absence of the President.

THE PRIZE ESSAYS.

The Committee on Prize Essays announced that eight essays had been presented in competition, and that the following were recommended as worthy of the award.

1. "On the cause of Intermittent and Remittent Fevers." With the motto, "Fortis est veritas."

2. "On the treatment of certain Abnormities of the Uterus." With the motto, "Empiricism in Medicine and Surgery is fast giving away to the rationalism of true diagnosis."

The envelopes, opened in presence of the delegates, were found to contain the names of (1) Dr. J. D. Black, Newark, Ohio, for the first prize, and (2) Dr. M. A. Pallen, St. Louis, Mo., for the second prize.

The papers were, on motion, referred to the Committee of Publication.

Dr. Cox then read an abstract of the Report of the Committee on American Medical Necrology. Referred to Committee as above.

THE REPORT OF THE CONVENTION OF MEDICAL TEACHERS.

Dr. Sayre offered the subjoined:

Resolved, That this Association most cordially approve of the whole action of the Convention of Delegates from Medical Colleges, assembled in Cincinnati, May 3, 1867, and urge its practical adoption by all the medical colleges in our country.

Dr. Post, of New York, wished to offer some change in the course of instruction proposed.

Dr. Davis reminded him that the college to which he was attached had been invited to be present and take part in the proceedings of that Convention, but had not seen fit to do so. He could at the next meeting of that Association offer any amendment he chose, but he claimed that this body had no power to act in the matter.

Dr. C. A. Lee, of Buffalo, though not present at the Medical College Convention, approved of all that was done. He had for many years, as a teacher in a medical college, contemplated just such changes as had been recommended.

The resolution was then adopted.

Dr. Bibbins moved that the resolution abolishing the payment of money for prizes be taken up.

After an animated discussion, in which Drs. Davis, Bronson, Bibbins, and others, participated, the original motion was tabled.

THE PROPOSED ANNUAL ASSESSMENT.

Dr. Toner moved, for present consideration, his resolution offered two years ago, calling for an amendment of the Constitution to the effect, that every permanent member pay a yearly due of five dollars, and as a penalty for neglecting the same for three successive years, be liable to have his name designated by a * or † in the catalogue triennially published.

The motion, after considerable debate, was finally withdrawn.

Dr. Robbins, of Ill., submitted the following:

Resolved, That hereafter the Committee of Arrangement be directed to have the ordinances governing the sections printed on slips, and distributed at the several places where the sections meet.

Carried.

Dr. Howard offered as follows:

Whereas, There has been issued, and still remains in force, an official order from the Surgeon-General of the United States Army, prohibiting the communication of any medical or surgical information, by any medical officer of the United States Army, to any person whatsoever, without special permission from the Medical Bureau at Washington; thus appropriating

as far as the official power of the Surgeon-General can compass it, all the valuable experience and statistics of all medical men who have served in the various departments of the United States Army to the exclusive use of the Medical Bureau; and,

WHEREAS, Under such arbitrary control an official report has already been made, tending to create incorrect impressions on scientific questions of great practical importance to the profession and to society; and

WHEREAS, It is important to the reputation of all men who served during the war, that they have the opportunity of correcting such erroneous impressions by an examination of the original records; therefore, be it

Resolved, That it is the opinion of this Association that the monopoly now exercised by the Medical Bureau over the medical and surgical records of the war, is contrary to the genius and catholic spirit of our profession, and obstructive to the highest interests of science and humanity.

Resolved, That the Secretary of War, or other proper authorities, be requested to direct that the original records of the medical and surgical history of the war be rendered accessible, on certain regular days of each month, for purposes of scientific investigation, to all medical men who have served as such in the army of the United States.

DR. HOWARD spoke at length in support of the resolution. He dwelt upon the jealousy of departments against interference on the part of outsiders. He did not aim at any one in particular, as a target; he spoke for the benefit of the profession.

DR. J. J. WOODWARD replied that he was opposed to having gentlemen come here to ventilate their private griefs, at the expense of the valuable time of this learned body. Especially was he opposed to it, when the remedy sought for these griefs, whatever it may be, cannot be applied except at the expense of great public interests, now being earnestly and honestly administered by the Surgeon-General, an able and conscientious officer. Dropping therefore such minor matters, he proposed simply to explain certain reasons for the attitude of the Surgeon-General.

In the first place, those most anxious for premature access to these records are not those who have contributed most largely to them. Too often, indeed, they belong to men who might have contributed much but who have contributed nothing, and who desire now to enjoy the fruits of the labors of others. It would be necessary to close the record against such men, even if no other reason for such a course existed. But, in the next place, it would be impossible to give such access to all the outsiders who desire it, prior to publication, without gravely interfering with the scientific labors now in progress and postponing, perhaps indefinitely, the publications now preparing.

It has been said that it is not certain when any of this material will be given to the profession. As to that he was not prepared to say too much, but this he would say, although he did not come here intending to announce it, that in the course of the next two months the Surgeon-General will give to the public as a first instalment of the labors he has undertaken for the good of the profession, an illustrated catalogue of the museum, which will contain about a thousand finely printed quarto pages, embracing among other things the histories of more than four thousand surgical cases of which we have specimens. (Great applause.) Other material will follow in due time; but for a work like this we need time. As regarded the correction of errors, the Surgeon-General had never opposed any obstacles whatever.

But there is another and still graver reason why the access asked cannot be granted. These records are not used for scientific purposes alone; they are employed in settling the pensions of the widows and orphans of our dead soldiers; and the bounty, back-pay, and pensions of the disabled; fifty searchers, as many as the nature of the records permit, are daily at work with them for this purpose; no outsider can be permitted to intrude, without gravely prejudicing this work, the execution of which is imperatively demanded by every consideration of humanity. When he left Washington there were about six thousand unanswered claims still upon his table. The question then before the Convention was simply this: Shall further obstacles be interposed to delay a work now being honestly executed? He hoped, therefore, for the seal of the Association's condemnation upon this attempt to meddle with a conscientious public servant, in the discharge of his duty. He would now move to lay these resolutions on the table. (Great applause.)

The motion to lay on the table was seconded and carried almost unanimously.

DR. COX presented advance proof-sheets of "Provisional Nomenclature of Disease," which was published in London. Referred to Section on Practical Medicine. Also another, "On Compulsory Vaccination," by Dr. A. N. Bell, of Brooklyn, New York, was presented by deputy, and, on motion, referred to the Committee on Hygiene.

DR. HAMMER offered a series of resolutions regarding certain proposed reforms in medical pupilage. Referred to Committee on Medical Education.

DR. R. H. GILBERT, of New York, exhibited an instrument for the protection of the periosteum in excisions, etc. Referred to Section on Surgery.

DR. POST read the report of the Committee on Medical Literature, in which he gave certain bibliographical items, referring to reports, etc.

DR. SAYRE criticised certain portions of the report as being too highly laudatory of the Board of Health of New York, and as containing matter foreign to the scope of such a production. He also made some remarks upon cholera and quarantine, and claimed that there were few if any cases of that disease to combat, and that these same had been introduced by breakages of the quarantine.

DR. DAVIS supported the spirit of the Committee's report, and moved that it take the usual course of reference to the Committee on Publication, which was adopted.

DR. HIBBARD offered the following:

Resolved, That the habit of using unofficinal preparations of medicine by physicians, except where there is no officinal preparation that will answer the purpose as well, is unscientific and imprudent, tending to demoralize the therapeutist and to encourage irregular pharmaceutists and nostrum makers, and should be abandoned.

Resolved, That the profession should not patronize druggists who are engaged in the manufacture of nostrums.

On motion, tabled.

The following papers, in the course of the meeting, were read by title, and disposed of as follows:

"Observations on Diseases of the Throat, as seen in the Military Service from 1861 to 1865." By Prof. M. K. Taylor, M.D. Referred to Section on Practical Medicine and Obstetrics.

"A Novel Case of Lithotomy," by Dr. Edward Whinnery, of Iowa.

"On Ligature of the Subclavian Artery," by Dr. Willard Parker, of N. Y.

Also, "On Hip-joint Operations," by Dr. Paul F. Eve, of Tennessee. All referred to Section on Surgery.

"On Compulsory Vaccination," by Dr. A. N. Bell. Referred to Committee on Meteorology, Medical Topography, and Epidemic Diseases.

The Secretary read an authenticated communication from the Chicago Medical Society, announcing the expulsion of Dr. Jonathan D. Brooks and Dr. N. Peterson from aforesaid body for violation of the Code of Medical Ethics. The names in question were ordered to be dropped from the roll of the American Medical Association.

A communication proposing that no person who is not a member and supporter of a local Medical Society, where such a one exists, shall be eligible to membership in the American Medical Association was, on motion, laid over until the next year, as duly provided for by the Constitution.

The Association then adjourned until 9 o'clock the following morning.

THIRD DAY, MAY 9, 1867.

DR. H. F. ASKEW, President, in the Chair.

MORNING SESSION.

The Association met at 9 o'clock pursuant to adjournment.

DR. D. H. STORER, of Mass., moved that a recess of five minutes be granted before the reading of Dr. Ray's paper, which had been set down as the order of the day. Carried.

DR. D. H. STORER then proposed that, inasmuch as the Treasury of the Association was somewhat in debt, a sufficient sum be raised at the present meeting to put it into a better financial condition.

A motion to levy an assessment of two dollars upon each member, with the understanding that the contribution should be voluntary, was made.

DR. C. A. LEE stated that he proposed the same method last year, and was most happy to second it.

DR. DAVIS, of Illinois, offered the following:

Resolved, That Dr. D. H. Storer be requested to draw up a subscription paper, and place it in a suitable locality, accessible to the members, and that all present be asked to subscribe such amount as they feel disposed for the purpose of liquidating the indebtedness of the Association and replenishing its treasury.

Adopted.

FEMALE MEDICAL EDUCATION.

DR. ATLEE, of Philadelphia, offered the following preamble and resolutions:

WHEREAS, The subject of female medical education is exciting attention, and regularly educated female physicians have established themselves as practitioners of medicine; and,

WHEREAS, Female medical colleges, embracing all branches taught in other colleges, and all their conditions for graduation, exist in the United States for the separate education of females; and,

WHEREAS, It is important that the standard of education and the observance of the code of medical ethics should be fostered and maintained by this Association; therefore,

Resolved, That the American Medical Association recognises well-educated female physicians by the same laws that govern its own members.

DR. BOWDITCH rose to a point of order. He reminded the President that the five minutes' recess had just expired, and would, therefore, move to lay the whole matter on the table. Carried.

REPORT OF COMMITTEE ON INSANITY.

DR. CLEMENT A. WALKER, of Massachusetts, apologized for the absence of Dr Ray, and stated that the precarious condition of Dr. R.'s health had impelled him to resign his position as Superintendent of the Asylum. He then read the Report of the Committee on Insanity. He combated many of the popular notions and even the professional theories on the subject. He alluded to the law of hereditary transmission, and maintained that insanity was controlled by some law of normal limitation, oftentimes requiring only an exciting cause.

Hereditary disease must have had an origin at some time, that it seldom passes through all its stages in a single individual. More than one generation is required to develop *all* the stages of the disease. The essential thing is nervous impairment. Cerebral vitiation, self-induced, strong distracted nervous irritation during pregnancy, are heritable. *All* the traits of one parent, however, cannot be expected to descend to any single individual of his offspring. Insanity is not therefore an unmitigated evil, not amenable to treatment. Recent investigations have developed the fact, that the obscurer forms of the malady were never previously recognised. The throwing of the veil of insanity over human delinquencies as a legal defence, has long stood in the way of a dispassionate investigation. Popular prejudice may defer the verdict but cannot affect the truth of science. He scouted the idea that the students of insanity, by a strange perversity, gradually come to consider that all are more or less insane. So then, the more thorough the investigation, the more fallacious the conclusions!

Monomania was not recognised until the present century. Moral perversion is an accident, not a necessary accompaniment of the malady. Considering the brain as the material instrument of the mind, it of course is subject to the operation of physical and extrinsic causes.

Insanity has no essential feature common to every case, but the people will not accept this axiom because it conflicts with old opinions. No metaphysical subtlety is, however, to be pitted against the deductions of common sense. Responsibility is an available plea only in disease, because in health the mind is also healthy.

Moral Insanity is therefore something more than a mere fiction.

As regards treatment, not to mention the various methods of purgation, emesis, etc., the most dangerous was founded on the theory that insanity was essentially inflammatory. He denounced the other modes of physical assault, powerful mental shocks, etc., and eulogized the more rational treatment of cheerful surroundings, etc.

DR. H. R. STORER moved the acceptance of the report and its reference to the Committee of Publication. Carried.

DR. CHIPLEY, of Lexington, Ky., offered some remarks in vindication of the Superintendents of Insane Asylums, with reference to their connection with this association. He alluded to the fact that there were five such Superintendents present, who were a larger proportion of their class than the representatives of any other class of the medical profession present. Regarding the allegation that a proper verdict could not be rendered except by the Superintendents, he would inquire whether all questions of trade were not referred to its own particular class.

During his speech Dr. Chipley paid a glowing tribute to the services of Miss Dix, who had done so much for the insane of the country.

The Committee on Nominations made the following report:

Place of meeting next year—New Orleans. Time—May.

OFFICERS FOR 1868.

President—Samuel D. Gross, Penn.

Vice-Presidents—1st, A. C. Post, N. Y.; 2d, John H. Atlee, Penn.; 3d, D. W. Yandell, Ky.; 4th, H. R. Storer, Mass.

Permanent Secretary—W. B. Atkinson, Philadelphia, Penn.

Assistant Secretary—J. G. Richardson, New Orleans.

Treasurer—Caspar Wistar, Philadelphia, Penn.

Committee of Arrangements—W. Storer, Warren Brickell, S. Chapin, John Foster, L. T. Pimm, S. M. Berniss, and C. Beard, all of New Orleans.

Committee on Medical Associations—H. B. Palmer, Mich.; W. H. Byford, Ill.; M. L. Linton, Mo.; Gustave C. E. Weber, Ohio; H. R. Storer, Mass.

The Committee on Medical Necrology was continued, with the following changes to supply vacancies:

John Shrady, N. Y.; J. M. Toner, D. C.; Thomas M. Doran, Cal.; A. G. Field, Iowa; H. F. Askew, Del.

Committee on Medical Literature—Geo. Mendenhall, R. R. McIlvain, Geo. C. Blackman, E. Williams, C. S. Connor, all of Cincinnati.

Epidemics and Climatology—W. F. Thoms, N. Y.; J. W. Hatch, Cal.; Joseph Jones, Tenn.; J. F. Heard, Texas; and E. K. Hart, Conn.—substituted for Dr. B. H. Catlin.

Committee on Prize Essays—Burnett Dawler, S. A. Smith, W. Brickell, S. M. Bemiss, J. Scott, all of New Orleans.

Committee on Publication—F. G. Smith, Caspar Wistar, W. B. Atkinson, W. Maybury, all of Pennsylvania; H. F. Askew, Delaware; H. R. Storer, Mass., and W. W. Dawson, Ohio.

Delegates to International Medical Congress—Drs. Paul F. Eve, Edmund Andrews, C. E. Brown-Séquard, Thomas M. Logan, R. R. McIlvain, John M. Kitchin, B. Fordyce Barker, Thos. C. Brinsmade, John E. Tyler, J. M. Toner, and Louis Elsberg.

The Committee recommended the adoption of the following:

Resolved, That the Committee suggest to the Association that, in future, the publishing committee be requested to publish the name of every member of each standing committee.

A motion that the report lay on the table until that of the minority of the Committee was read, was declared lost.

Dr. Davis moved that the report of the Committee be accepted, and their resolution adopted. Carried.

Dr. Bibbins, of N. Y., asked the reason why New Orleans was named, and whether or not any delegate from Louisiana was present.

Dr. Davis moved that the portion referring to the proposed place of meeting, together with the special local Committees and local Secretary, be laid on the table. Carried.

The report of the Nominating Committee, with the exceptions indicated, was then adopted.

Dr. Davis then called up the part of the report regarding the place of meeting, and again protested against the selection of New Orleans, on various grounds. He presented the following:

"*Resolved*, That the next annual meeting of the American Medical Association shall be held in the City of Washington on the first Tuesday in May, 1868, and every second year thereafter, until otherwise ordered by the Association.

"*Resolved*, that whenever the Association shall meet in the City of Washington, as directed in the above resolution, the Committee of Arrangements be strictly forbidden either to provide themselves, or accept provision by others, of any entertainment or excursion whatever."

Dr. Yandell, of Ky., spoke eloquently in behalf of a profession which no war had ever yet disunited, and claimed for his brethren of the South the privilege of entertaining the Association.

Dr. Griswold, of Ohio, moved the substitution of Knoxville, Tenn., for Washington, D. C.

Dr. Sayre moved to substitute New Orleans, as in the original report. He thought that, with Dr. Davis's resolution of restriction as to entertainments, there would be no objection to that place.

Dr. Cox endorsed all that had been said by his friend from Kentucky; was proud that one man from the South had expressed himself as standing on the platform of the union of the medical profession. He never supposed there would be any difficulty in reuniting the profession of medicine after the war was over. As to the entertainments of the Association, he was in favor of them, and thought if Dr. Davis's measure was adopted the usefulness and attendance of the Association would be impaired. In England they did far more eating and drinking than was done here, and yet they accomplished a large amount of work.

Dr. D. H. Storer, of Boston, said the object of these meetings was to bring as many of the profession together as possible, and it should meet in such places as would accomplish that object. We should not meet where we have not been invited by resident members. The probability was, we would be well received, but we ought to wait for a proper invitation.

A motion to postpone the discussion until the next Session then prevailed, after which the Association adjourned to meet at 3 P.M.

AFTERNOON SESSION.

The Association met and adjourned, there being no quorum present.

Friday, May 10, 1867.

FOURTH DAY.

Dr. H. F. Askew, President, in the Chair.

Drs. J. D. Staebler, J. P. Walker, and P. F. Maley, of Cincinnati, Ohio; Dr. G. M. Kellogg, of Keokuk, Iowa; Dr. A. J. Larey, of Mount Pleasant, Kansas; Dr. Wm. Marsden, of Quebec; Dr. John Dillard, of Lexington, Kentucky; Drs. S. S. Gray, and A. S. Ashton, of Piqua, Ohio, were made members of the Association by invitation.

THE CASE OF DR. HINKLE.

A delegate presented papers involving charges against Dr. F. Hinkle, and asked that his name be stricken from the roll of members.

Dr. Atkinson, in presenting Dr. Hinkle's defence, moved a reference of the whole matter to the Committee of Medical Ethics.

The Chair ruled that the reference was out of order, and decided that Dr. Hinkle's name be erased.

ADDITIONAL DELEGATES TO INTERNATIONAL CONGRESS.

The following were, on motion, elected additional delegates to the International Medical Congress to be held in Paris next August.

Drs. Wilson Jewell, of Pennsylvania; Ninian Pinkney, U. S. N.; John Hart, of New York; and Charles A. Pope, of Missouri.

Dr. Hibbard, of Illinois, then presented the following, which was carried.

Whereas, It has been officially announced that for the last two years the annual volume of Transactions of this Association could be published only by the members of the Publication Committee becoming individually responsible for the cost of the same above the amount of funds in the treasury; and

Whereas, Such a condition of affairs is impolitic for the Association and unjust for the Committee: therefore

Resolved, That the Association does not expect the Committee on Publication to issue the volume of Transactions for the present year, unless it can be done with the funds and the credit of the Association.

Dr. Hildreth submitted a resolution.

"That a Committee on Ophthalmology be appointed to report at the next session."

Adopted.

Drs. Joseph S. Hildreth, of Chicago, Illinois, Henry D. Noyes, and Cornelius R. Agnew, of New York, were appointed said Committee.

THE NEXT PLACE OF MEETING TO BE WASHINGTON, D. C.

Dr. Davis's resolutions regarding the next place of meeting, etc., were then ordered from the table.

Dr. Hammer suggested St. Louis, Mo., as having favorable claims for the consideration of the Association.

After a lively debate, during which several amendments to the original resolution were entertained, the motion finally prevailed in the following form:

Resolved, That the next annual meeting of the American Medical Association shall be held in the city of Washington on the first Tuesday in May, 1868, and every second year thereafter, until otherwise ordered by the Association.

Resolved, That whenever the Association shall meet in the city of Washington, or elsewhere, as directed in the above resolution, the Committee of Arrangements be strictly forbidden either to provide themselves, or accept provision by others, of any entertainment or excursion whatever, which will conflict with the regular business of the body or its Sections.

CULTIVATION OF THE CINCHONA TREE.

Dr. Atkinson read a communication from Dr. Henry F. Lyster, Secretary of the Wayne Co. (Mich.) Medical Society, requesting that some action be taken by the American Medical Association regarding the "Introduction of the cinchona tree in the United States." For the sake of giving form to the discussion, he presented the subjoined:

Resolved, That a Committee of three be appointed by the Chair, whose duty shall be to memorialize Congress relative to the cultivation of the Cinchona tree.

Carried.

Drs. J. M. Toner, and F. Howard, of Washington, D. C., and Dr. C. A. Lee, of Poughkeepsie, N. Y., were appointed said Committee.

Dr. Atkinson read by title a paper from Dr. E. Harris, of N. Y., upon the "Causes of Cholera." Also another by Dr. E. Krackowizer, on "Local Anæsthesia."

Dr. Davis, in view of the fact that the hour of adjournment was rapidly approaching, offered a resolution which he thought would meet all objections.

Resolved, That such papers and reports as the several Sections have not been able to act upon, be referred to a Special Committee of *three*, to examine and act upon in all respects as is required in the proper Sections.

Carried.

The Committee as appointed consisted of Drs. N. S. Davis, D. H. Storer, and C. A. Lee.

Dr. Harris's and Dr. Krackowizer's papers were then, on motion, referred to said Committee.

Dr. Atkinson read by title "Synopsis of an Essay on the Contagion, Infection, Portability, and Communicability of the Asiatic Cholera in its relations to Quarantine. With a brief history of its origin and course in Canada, from 1832. By Wm. Marsden, M.D."

Dr. Marsden made a few remarks in explanation of the objects, etc., of the paper.

Dr. Sayre moved to refer the paper to the Committee of Publication. Carried.

ALTERATIONS IN THE PLAN OF ORGANIZATION.

The following was offered by Dr. Cox, of Maryland:

Resolved, That a committee of five be appointed by the Chair to take into consideration such amendments or alterations in the plan of organization of this Association, and to remedy defects, if any, and increase its efficiency, and report at the meeting in 1868. Adopted.

Drs. C. C. Cox, J. M. Toner, W. B. Atkinson, J. J. Woodward, and John Shrady, were appointed in accordance with the above.

Dr. Davis moved that the resolution referring Dr. Marsden's paper to the Committee of Publication be reconsidered. Carried.

The motion to refer said paper to the special committee as previously provided, was then carried.

Dr. B. Howard, of N. Y., owing to the absence of the Secretary, read the report of the Surgical Section, which, after some corrections, was accepted.

CHOLERA AND QUARANTINE.

Dr. Charles A. Lee, of New York, then submitted these resolutions, bearing upon the subject of Cholera, which were adopted as the sense of the Convention.

Whereas, it was declared by a vote of Congress at its last session, that it is not within the Constitutional powers of the General Government to establish a general and uniform system of quarantine for the different ports of the United States, and Whereas, the cholera infection has been introduced into the United States, and did doubtless manifest itself in many of the cities, towns, and villages, of our country during the present season, and

Whereas, the experience of the city of New York and other places, both at home and abroad, has demonstrated the efficacy of certain chemical disinfectants, especially *carbolic acid* and the *sulphate of iron*, in destroying or preventing the spread of cholera *virus*, it is hereby as urgently recommended by this Association, that the attention of physicians of the United States be chiefly and constantly directed to the prompt and free use of such disinfectants wherever the cholera poison may show itself,—

Resolved, That as the experience of Europe and the United States has satisfactorily shown that the cholera poison cannot be controlled or kept in check except where the *cordons sanitaires* are absolutely prohibitory of all intercourse, as was the case in the entire Island of Sicily, and the entire coasts and frontier of Greece, during the recent cholera epidemic, and,

Whereas, there is no good reason to believe that the people of the United States would not submit to the enforcement of such prohibitory measures, and non intercourse, as is necessary to hold the cholera poison in check, especially after its introduction into the country, it is hereby recommended to all municipal bodies and Boards of Health to pay special attention to requisite sanitary measures, such as the cleansing of streets, lanes, and alleys; the supply of pure drinking water to the inhabitants; the ample provision of chemical disinfectants, and their prompt employment in necessary cases; the separation of the sick from the healthy, in the same dwelling; the inspection and regulation of tenement houses; the provision of nurses, hospitals, and competent physicians for the sick poor, who may be attacked; provision for early burials of the dead; the separation of the corpses from the living; and the prohibition of the custom of waking the dead, and all other measures which have been found necessary to control the progress of the disease

Resolved, That experience proves that the publication of the facts connected with the existence and progress of cholera in any place, instead of disturbing the popular mind, while it reveals the exact extent of the danger, robs it of the hold of alarm and fear, with which the imagination surrounds indefinite pestilence, walking abroad by noon-day.

Dr. H. R. Storer read the minutes of the section on Psychology, which were on motion referred to the Committee of Publication.

The reports of the section on Practical Medicine, and on Meteorology, were read and disposed of in like manner.

The Committee on Nominations submitted their report as amended. The changes are:

Committee of Arrangements.— Drs. Grafton Tyler (Chairman); William P. Johnson, F. Howard, William Maybury, Lewis Mackall, T. F. Many, J. M. Toner, *Assistant Secretary*, J. W. H. Lovejoy; Added to *Com. on Necrology* Dr. Samuel Willey, of Minnesota; and Dr. Samuel M. Welch, of Galveston, Texas.

REMUNERATION OF PERMANENT SECRETARY.

DR. M. A. PALLEN presented the subjoined:

Whereas, it was the intention of the resolution originally introduced, creating the office of Permanent Secretary, to pay said officer a certain sum annually, as a salary for services as such; and, Whereas, Dr. William B. Atkinson, our present efficient and urbane Secretary, has never received any money whatsoever in payment of said services, therefore,

Be it resolved, that the Permanent Secretary hereafter, and from this date, be authorized to draw a warrant upon the Treasurer for the expenses incurred in his attending each session of the Association, and that the Treasurer is hereby instructed to pay the same.

Unanimously adopted.

DR. ATLEE moved that the thanks of the Association be tendered to the Permanent Secretary, for past services. Carried.

THE ANNUAL ASSESSMENT AGAIN.

DR. TONER proposed the following, which includes an article of the Constitution with the amendments added: The sum of five dollars shall be assessed annually upon each delegate to the Sessions of the Association, as well as upon each of its permanent members, whether attending or not, for the purpose of raising a fund to defray the *necessary* expenses of the Association, and for printing the Transactions. The payment of this assessment shall be required of the delegates and members in attendance upon the Sessions of the Association previously to their taking seats and participating in the business of the session. Permanent members not attending, shall forward their yearly dues to the Treasurer, and thereby shall be entitled to receive a copy of the printed Transactions, the same as delegates. Referred, after an animated debate, to Committee on Revision of Constitution and By-Laws.

DR. HIBBARD asked that Dr. H. R. Storer be permitted to use, in the preparation of a paper, certain matter previously presented by himself to the Association. Permission granted.

Votes of thanks to various railroad companies, and others, for courtesies extended the Association, were then passed.

DR. HIBBARD'S resolutions, regarding the use of unofficinal preparations, and the relations between the profession and the venders of nostrums, were then called up.

DR. POST called attention to the proper distinctions between the terms, "unofficinal" and "magisterial."

DR. COX, as an amendment, desired to insert after *manufacturing*, the words, "advertising or selling quack medicines or nostrums." Lost.

DR. BIBBINS moved the reference of the whole subject to the Committee on Revision of the Constitution, etc. Carried.

FEMALE EDUCATION AGAIN.

DR. ATLEE then pressed his resolutions on the subject of Female Medical Education. A motion to take them from the table was carried by a vote of 56 to 52.

DR. PALLEN, of Missouri, was opposed to the discussion of the subject. Women were not by nature fitted for the practice of medicine. It had been tried in Europe, and had proved an utter failure. Ladies possessed of any delicacy could not acquire the proper amount of knowledge. Imagine a young lady, with gigantic chignon and garbed in silks, entering the charnel-house, and bending over a corpse, microscope in hand, searching for cancer cells, etc., etc.

DR. DAVIS thought the discussion of this subject, at this time, would only furnish newspaper gossips with a subject, and could do no possible good. He therefore moved to refer the whole subject to the Committee on Medical Ethics.

DR. BOWDITCH, of Mass, was opposed to this way of disposing of such an important matter. He had moved yesterday to lay the resolutions on the table, simply because he thought the Convention was not then prepared to act upon them. The question had nothing to do with the laws of nature or the manner in which ladies were to acquire the proper amount of knowledge. The question was simply whether or not they should be recognised when they *had* acquired that knowledge, as many of them undoubtedly had.

The Doctor mentioned several instances in which the practice of medicine by lady physicians had been attended with great success.

DR. DAVIS'S motion to refer to Committee on Medical Ethics was carried by a large majority.

DR. HIBBARD moved that Dr. Theophilus Parvin, of Indiana, be appointed to render a special report on the Surgical Diseases of Women, at the next annual meeting. Adopted.

A vote of thanks was tendered to Mr. F. Hopkins, for free use of his Hall.

A communication from Dr. J. Homberger, expressing his desire to resign from the Association, was received, and finally referred to Committee on Medical Ethics.

After a resolution, offered by Dr. S. C. Hughes, thanking the Press for impartial reports of the proceedings, Dr. C. A. Lee read the following:

THE PROVISION FOR CHRONIC INSANE.

Resolved, That providing for the poor chronic insane in the jails and almshouses of our country, as at present practised in nearly all the States of the Union, is a gross violation of the laws of humanity, and contrary to the Divine injunction of "doing to others as we would be done by."

Resolved, That where the regular hospitals for the insane of a State are insufficient to accommodate both acute and chronic cases that are sent to them, this Association would strongly recommend the procurement of a suitable amount of land in the vicinity, and the erection of convenient, well-planned, and well-ventilated, but comparatively inexpensive buildings, in connexion with and under the same general supervision as the hospitals themselves, where those who are able to labor, and would be benefited by light and regulated employment, may be suitably accommodated and properly cared for.

Resolved, That the example of Massachusetts in establishing asylums for the accommodation and humane treatment of the chronic insane, is worthy of all praise and imitation, and in the opinion of this Association, such institutions, if rightly inaugurated and judiciously carried on, will be a benefit to the State in an economical point of view, will raise the character of the State Hospitals, and will greatly subserve the interests of the insane generally.

Resolved, That as the present insane hospitals are capable of accommodating but a small proportion of the 40,000 insane of the United States, and as almshouse and jail provision is not adapted to their proper care and treatment, this Association would recommend to the proper State authorities, to make such further provision in the direction above indicated as may tend to the amelioration of their condition, if not the restoration of their rational and moral faculties.

Adopted.

DR. BIBBINS moved to refer to a Special Committee of five, to report to the next annual meeting. Carried.

Dr. C. A. Lee, N. Y.; Dr. Guntry, Ohio; Dr. John Fonerdin; Dr. Walker, Mass.; Dr. Chipley, Ky., were appointed said Committee.

Dr. Cox submitted the below-named resolutions, which were unanimously adopted:

THE LATE SURGEON C. S. TRIPLER, U.S.A.

Resolved, That in the loss of Surgeon Charles S. Tripler, U. S. A., who died in this city since the last meeting of the Association, the profession throughout the country, the army of the United States, and the Society especially, have experienced a serious loss.

Resolved, That in the high moral integrity, Christian character, professional ability, and conscientious love of his vocation, we recognise in Dr. Tripler one of the truest illustrations of a sound physician and a good man.

Resolved, That the condolence and sympathies of this Association are hereby tendered to the family and relations of the deceased; and the Secretary is directed to communicate to them a copy of these resolutions.

Dr. Davis moved that the Committee charged with procuring suitable accommodations for the Association meetings in the Smithsonian Institution, in Washington, D. C, be continued. Carried.

Dr. Alden March, of New York, offered the following:

Resolved, That the thanks of the Association are due, and are hereby tendered to the President and retiring officers for the ability, impartiality, and courtesy manifested in the discharge of their arduous duties.

Carried.

Dr. Cox moved that surplus copies of the Transactions of the Association not yet out of print, be sent to the Secretaries of similar organizations in exchange for the volumes published by their own bodies. Carried.

Dr. Hughes presented the following:

Resolved, That those members of the Association who have contributed to the amount of five dollars to the publishing of future Transactions, shall be entitled to any back volume of the Transactions to the amount of same, as they may want.

Carried.

After the passage of several votes of thanks the meeting adjourned at two P. M., to meet at the time and place previously designated.

Meeting of Sections.

SURGICAL SECTION.

Sessions at the Medical College of Ohio, May 7 and 9, 1867.

The meeting was called to order at 3 P.M. Prof. S. D. Gross, M.D., of Philadelphia, was appointed Chairman, and Dr. J. L. Little, of New York, Secretary.

Dr. Joseph S. Hildreth, of Chicago, Ill., read a paper "On the Action of Belladonna in Diseases of the Cornea." The writer maintains that in certain conditions of the eye, the nervous integrity of the cornea may be so disturbed as to cause a peculiar state of anæsthesia. The dilatability of the pupil is correspondingly lessened, and the effects of atropia are of short duration. There may be either an acute or a chronic form of anæsthesia. In corneal affections with an anæsthesia and diminished dilatability of the pupils, belladonna is indicated, but with normal dilatability of the pupil and absence of corneal anæsthesia, belladonna is not required. A thorough division of the ciliary ring, and not the evacuation of the aqueous humor, affords relief for corneal anæsthesia. Paracentesis of the anterior chamber may, in some cases of this class, prove serviceable by diminishing congestion of the ciliary ring, but not otherwise.

Iridectomy, in one case, notwithstanding that it removed all intra-ocular tension, failed to relieve the corneal anæsthesia. Division of the ciliary ring, fifteen minutes afterwards, at once accomplished that result.

Dr. Hammer remarked that according to Donders, corneal ulceration was due, not to any nervous lesion, but to the lodgment of particles upon the cornea, the presence of which was not noted by the anæsthetic cornea.

Dr. Hildreth thought that the experiments of Magendie, which he would not then recite, proved directly the reverse.

Dr. Gross entertained a similar opinion.

Dr. Hildreth's paper was, on motion, referred to Committee of Publication.

"A Report on the Use of Plaster of Paris in Surgery," by Dr. James L. Little, of New York, was similarly referred.

Dr. B. Howard, of New York, read a paper entitled "Ligation, with Depletion of Varicose Veins of the Leg, with a Case of Radical Cure."

The operation consisted in first distending the veins, by causing the patient to stand upon the leg affected. A stout unarmed aneurism needle was passed behind the vein, just above the internal malleolus, and its points caused to emerge on the opposite side. The needle being then armed with a silver wire ligature, withdrawn, and disarmed, both free ends were left ready to be fastened. This process was repeated at nine different points.

The ligature first applied was secured by passing both its free ends through a hole in a small leaden disc, which was capped by a perforation of buckshot. Forcible compression with a common plyers completed the manipulation. The two ligatures in the popliteal regions were similarly disposed of.

The vein between these extreme points was then punctured in several places, and the blood allowed to escape, which it did rather freely. All the ligatures were then secured.

Paper referred to Committee of Publication.

The following, after having been read, were likewise referred to the same Committee.

On a New Method of Operating on the Bones for the lengthening of the same. By Dr. J. C. Hughes, of Iowa.

A Report on the Ligature of the Subclavian Artery. By Willard Parker, M.D., of N. Y.

A contribution to the Hip-joint operations during the late civil war, being the statistics of twenty cases of Amputations, and thirteen of Resections of this Articulation in the Southern States, by Paul F. Eve, M.D., of Nashville.

A collection of cases of Lumbar Colotomy (Amussat's operation), by Dr. Geo. C. Blackman, of Cincinnati.

The following papers were laid on the table:

Observations on Rhinoscopy, by Lawrence Turnbull, M.D., of Philadelphia.

A paper on the Bibliography and Observations on the present condition of Aural Surgery, by Lawrence Turnbull, M.D., of Philadelphia.

On the treatment of Hernia, by Chauncy F. Perkins, M.D.

A novel case of Lithotomy, by Edw. Whinnery, M.D., of Iowa.

The following committees were appointed to report at the next Annual Meeting:

On the Ligation of Arteries, Benj. Howard, M.D., of New York, Chairman.

On the treatment of Club-foot without Tenotomy, Lewis A. Sayre, of New York, Chairman.

On the Radical Cure of Hernia, Geo. C. Blackman, M.D., of Cincinnati, Chairman.

On the Operations for Hare-lip, Dr. Hammer, of St. Louis, Chairman.

On the Errors of Diagnosis in Abdominal Tumors, G. C. E. Weber, of Ohio, Chairman.

The Section then adjourned *sine die.*

SECTION OF PRACTICE OF MEDICINE AND OBSTETRICS.

SESSION AT THE DENTAL COLLEGE, THURSDAY, MAY 7TH.

The section having convened at 3 P.M., Prof. M. K. Taylor, of Keokuk, Iowa, was elected Chairman, and Dr. Edward Hall, of Auburn, New York, Secretary.

An abstract of a report on the Therapeutics of Inhalation (J. Solis Cohen, J. A. Da Costa, and Louis Elsberg, committee) was read, and laid upon the table until the report itself could be brought before the section.

Dr. Joseph G. Richardson, of New York, read a paper entitled "Clinical Thermometry in Diphtheria." From numerous observations made by the author he had become convinced that while the membrane is forming and rapidly extending, the heat of the body increases, and returns to the normal standard as the membrane disappears. The temperature of the body, therefore, affords one of the most valuable indications in the prognosis and treatment of this disease.

An interesting discussion in regard to the temperature of the body, not only in diphtheria, but in other diseases, took place, participated in by Profs. Johnson, Palmer, Comegys, Dr. Severens, Dr. Williams, and others. It was finally voted that the author be requested to continue his investigations, and report at the next meeting of the Association.

An unfinished paper, by Dr. A. G. Field, of Iowa, on the "Treatment of Disease by Atomized Substances," was presented, and the author was requested to read the same completed at a future meeting.

Portions of a paper by Dr. Stephen Rogers, of New York, on "Extra-Uterine Fætation and Gestation," containing a statement of the symptoms, and recommending abdominal section, in order to meet the indications, were read. It was voted to recommend it for publication in the Transactions. Remarks were made by Profs. H. R. Storer, Palmer, Byford, Dr. Parvin, and others, after which the section adjourned.

SESSION, MAY 9, 1867.

The section was called to order at 4 P.M. Dr. Hibbard in the chair.

The minutes of the last meeting were read and approved.

The Secretary reported that he had been unable to procure the report on the "Therapeutics of Inhalation."

After some discussion, it was voted to recommend to the Association to give the Committee on Publication discretionary power in regard to printing this report, or portions thereof, in the Transactions.

Prof. M. K. TAYLOR, of Keokuk, read a paper entitled, "Remarks on the Diseases of the Heart, as observed in the military service, 1861–5."

He remarked that in many men debilitated by malarious and other diseases, and hardship, a condition of the heart existed similar to hypertrophy. These cases resulted from a loss of muscular tone; were not serious, and were restored to health after a lengthy period of rest, and treatment of a tonic and hygienic nature.

DR. BOWDITCH had observed a similar condition in soldiers whom he had examined, as had also Dr. Gross, at Pittsburgh, Penn.

DR. HALL, of N. Y., remarked that in his examinations of several hundred returned soldiers, he had frequently detected the same cardiac condition accurately described in the paper read by Prof. Taylor.

The paper was recommended for publication in the Transactions.

The minutes of this meeting were read and approved, and the section adjourned *sine die.*

SECTION ON METEOROLOGY, MEDICAL TOPOGRAPHY, ETC.

SESSION, MAY 7, 1867.

DR. B. H. CATLIN, of Conn., was called to the chair, and DR. N. S. DAVIS, of Ill., appointed Secretary.

DR. HAMMIL read an interesting report on the Climatology of Illinois, giving reports of the sanitary condition and mortality rates of Chicago. He referred to the singular fact that in Illinois cerebro-spinal meningitis was more prevalent than in any other State.

DR. DAVIS pointed out the fact that erysipelas was once very prevalent along the watercourses crimsoned by the blood of many slaughtered animals, and that the intensity of type was proportionate to the depth of tint.

Adjourned until Thursday.

SESSION, MAY 9, 1867.

DR. DAVIS read a paper on the "Causes of Cholera," as previously appointed, after which the meeting soon adjourned.

Paper referred to Committee of Publication.

SECTION ON PSYCHOLOGY.

The Section of Psychology was organized by the election of Prof. Chas. A. Lee, as Chairman, and Prof. H. R. Storer as Secretary.

After remarks had been made by several of the members present, it was determined to recommend to the Association the names of the following gentlemen as a Committee to report upon the subject of insanity at the ensuing meeting:

Drs. Chas. A. Lee, of N. Y.; John B. Chapin, of N. Y.; A. B. Palmer, of Michigan; W. W. Jones, of Ohio; H. R. Storer, of Mass.

Upon motion of Dr. Toner, the meeting was then adjourned.

Convention of Medical Teachers.

CONVENTION OF TEACHERS OF THE MEDICAL COLLEGES.

PROF. A. STILLÉ, President, in the Chair.

MORNING SESSION.

CINCINNATI, May 3, 1867.

THE delegates met at ten o'clock in the Faculty Room of the Medical College of Ohio, and organized by the choice of Professors A. Stillé, of Philadelphia, Penn., as President; and Prof. Gustav C. E. Weber, of Cleveland, Ohio, as Secretary. After a brief service by those gentlemen, in a temporary character, the following were recognized as delegates:

Professors A. Hammer, of Humboldt Medical College, St. Louis, Missouri; W. H. Byford, Chicago Medical College, Chicago; A. Stillé, University of Pennsylvania, Philadelphia, Pennsylvania; A. B. Palmer, University of Michigan, Michigan; A. B. Palmer, Berkshire Medical College, Massachusetts; Alden March, Albany Medical College, New York; A. J. Steele, Chicago Medical College, Chicago; N. S. Davis, Chicago Medical College, Chicago; Francis Carter, Starling Medical College, Ohio; James M. Holloway, University of Louisville, Kentucky; N. R. Taylor, Medical Department of Iowa University, Iowa; J. C. Hughes, Medical Department

of Iowa University, Iowa; G. C. E. Weber, Charity Hospital Medical College, Cleveland, Ohio; F. Donaldson, University of Maryland, Maryland; J. N. McDowell, Missouri Medical College, Missouri; C. G. Comegys, Medical College of Ohio, Ohio; George C. Blackman, Medical College of Ohio, Ohio; E. B. Stevens, Miami Medical College, Ohio; George Mendenhall, Miami Medical College, Ohio; S. D. Gross, Jefferson Medical College, Pennsylvania; B. L. Lawson, Cincinnati College of Medicine; —— Read, Cincinnati College of Medicine.

Professors Holloway, of Louisville; Davis, of Chicago; Donaldson, of Baltimore; Blackman, of Cincinnati; and March, of Albany; were appointed a committee to report on the order of the different subjects which were to occupy the attention of the Convention.

After which the convention adjourned till four o'clock P.M.

AFTERNOON SESSION.

The committee on the "Order of the Different Subjects to be presented for Consideration," reported the following propositions:

"1. That every student applying for matriculation in a Medical College, shall be required to show, either by satisfactory certificates or by a direct examination by a committee of the faculty, that he possesses a thorough knowledge of the common English branches of education, including the first series of mathematics and the natural sciences, and that the certificates presented or the results of the examinations thus required, be regularly filed as a part of the records of each medical college.

"2. That every medical student be required to study not only three full years, but also to attend three regular annual courses of medical college instruction before being admitted to an examination for the degree of Doctor of Medicine.

"3. That the *minimum* duration of a regular annual lecture term, or course of medical college instruction, shall be five calendar months.

"4. That every medical college shall embrace in its curriculum at least *thirteen* professorships, including substantially the following branches, namely: Descriptive Anatomy, Physiology and Histology, Inorganic Chemistry, Materia Medica, Organic Chemistry and Toxicology, General Pathology and Public Hygiene, Surgical Anatomy and Operations of Surgery, Medical Jurisprudence, Practice of Medicine, Practice of Surgery, Obstetrics and Diseases of Women, Clinical Medicine and Clinical Surgery. That these several branches shall be divided into three groups or series, corresponding with the three years required for medical study. The first, or freshmen series, shall embrace, Descriptive Anatomy, Physiology and Histology, Inorganic Chemistry and Materia Medica. To these the attention of the student shall be mainly restricted during the first year of his studies, and on them he shall be thoroughly examined by the proper members of the faculty at the close of his first course of medical college instruction, and receive a certificate indicating the degree of his progress. The second, or junior series, shall embrace Organic Chemistry and Toxicology, General Pathology, Public Hygiene, Surgical Anatomy and Operations of Surgery and Medical Jurisprudence. To these the attention of the medical student shall be directed during the second year of his studies, and on them he shall be examined at the close of his second course of medical college instruction, the same as after the first. The third, or senior series, shall embrace Practical Medicine, Practical Surgery, Obstetrics and Diseases of Women, with Clinical Medicine and Clinical Surgery in hospital. These shall occupy the attention of the student during the third year of his medical studies, and at the close of the third course of medical college attendance, he shall undergo a general examination in all the departments, as a prerequisite for the degree of Doctor of Medicine.

"The instruction in the three series of branches is to be given simultaneously, and to continue throughout the whole of each annual college term; each student attending the lectures on such branches as belong to his period of progress in study, in the same manner as the Sophomore, Junior, and Senior classes each pursue their respective studies simultaneously throughout the collegiate year, in all our literary colleges.

"5. That the practice of selling individual tickets by members of medical college faculties, should be abolished, and, in place of it, each student should be charged a specified sum for each annual course of medical college instruction; the sum being the same for each of the three courses before graduating; and any student or practitioner who has attended three full courses in any one college, shall be entitled to attend any subsequent course or courses in that college gratuitously. The fees paid for each annual course of college instruction should be paid to the Treasurer of the college, and subsequently distributed to each member of the Faculty at such time and in such proportion as the Trustees and Faculty of each college shall determine.

6. That inasmuch as the maintenance of an efficient Medical College requires a large expenditure of money annually, and inasmuch as there is no reasonable hope of adequate endowments from the several State governments, the exaction of a just and reasonable annual lecture fee is a necessity with which all medical colleges should comply, and that $105 should be the minimum fee for each regular annual course of instruction in any medical college in the United States."

The first proposition was taken up and discussed by Professors Davis, Gross, Comegys, McDowell, Hammer, Taylor, and Palmer, and with an amendment, so as to strike out the words "natural sciences," and add "sufficient knowledge of Latin and Greek to understand the technical terms of the profession," it was adopted.

The Convention then adjourned to meet at nine and a half o'clock on the morrow.

SECOND DAY—MAY 4, 1867.

MORNING SESSION.

PROF. A. STILLÉ, President, in the Chair.

The minutes of the preceding session were read and adopted.

The Chair announced that the next business in order was the discussion of Section 2 of the Report of the Committee on the Order of Business.

Professor Gross, of Philadelphia, moved to amend, so as to insert "four" after study, instead of "three."

Remarks were made by Professors Gross, Hammer, of St. Louis; Davis, of Chicago; Palmer, of Michigan; and McDowell, of St. Louis.

The Convention then suspended the rules, for the purpose of allowing Professor Davis to introduce the following resolution:

"*Resolved*, That in all distinct propositions under the consideration of this Convention, no member shall speak more than once until all other members have spoken who wish to speak." Adopted.

Prof. W. Howard, of Washington City, moved to amend by inserting "not less than three years," instead of "three full years." Lost.

Prof. Gross's amendment was then adopted.

On motion of Prof. Gross, the entire section, as amended, was unanimously adopted.

Prof. Hammer moved to take up for consideration Section 4, prior to Section 3. Lost.

Section 3 was read, viz.: "That the minimum dura-

tion of a regular annual lecture term or course of medical college instruction shall be five calendar months."

Prof. Gross moved to amend by inserting "six" in place of "five calendar months." Carried.

Section 3, as amended, was then adopted.

Section 4 being next in order, came up for discussion. Prof. Gross moved to discuss the different parts of this section separately. First, that relating to the different branches recommended to be taught in the schools. Second, the number of professorships. Third, the division of studies. Adopted.

Prof. Hammer moved to add to the different branches Natural Philosophy and Pathological Anatomy.

Prof. Donaldson, of Baltimore, moved to act upon these propositions separately.

The vote on the addition of Natural Philosophy being taken, it was rejected.

The amendment adding Pathological Anatomy was carried.

Professor Byford, of Chicago, moved to amend by including diseases of children. Carried.

On motion, the Convention then adjourned to meet at 4 o'clock.

AFTERNOON SESSION.

The meeting having been called to order, the second part of Section 4 was called up for discussion.

Professor Gross moved to amend by inserting after the words "following branches," "to be taught by not less than nine Professors." Carried.

Remarks were made by Professors Gross, Palmer, Davis, Hammer, Howard, and Taylor.

The third part of Section 4, referring to the division of studies, was next considered.

Professor Davis moved to amend, by making that part read as follows:

"That these several branches shall be divided into three groups or series, corresponding with the three courses of medical college instruction required.

"The first, or Freshman series, shall embrace Descriptive Anatomy and Practical Dissections, Physiology and Histology, Inorganic Chemistry and Materia Medica, and Therapeutics.

"To these the attention of the student shall be mainly restricted during his first course of medical college instruction, and in these he shall submit to a thorough examination by the proper members of the Faculty, at its close, and receive a certificate indicating the degree of his progress.

"The second, or Junior series, shall embrace Organic Chemistry and Toxicology, General Pathology, Morbid Anatomy and Public Hygiene, Surgical Anatomy and Operations of Surgery, and Medical Jurisprudence. To these the attention of the medical student shall be directed during his second course of medical college instruction, and in them he shall be examined at the close of his second course in the same manner as after the first.

"The third, or Senior series, shall embrace Practical Medicine, Practical Surgery, Obstetrics and diseases peculiar to women and children, with Clinical Medicine and Clinical Surgery in hospital. These shall occupy the attention of the student during his third course of college instruction, and at its close he shall be eligible to a general examination on all the branches as a prerequisite for the degree of Doctor of Medicine. The instruction in the three series of branches is to be given simultaneously, and to continue throughout the whole of each annual college term; each student attending the lectures on such branches as belong to his period of progress in study, in the same manner as the Sophomore, and Junior and Senior classes, each pursue their respective studies simultaneously throughout the collegiate year, in all our literary colleges."

After a protracted debate, in which Professors Gross, Palmer, Blackman, Hammer, Davis, and Taylor participated, the motion of Professor Davis prevailed.

Professor Davis then moved the adoption of the entire section as amended. Carried.

Section 5 was then taken up, and, upon motion of Professor Palmer, laid on the table.

Section 6 being in order, was read, but on motion of Professor Gross was also laid upon the table until Monday morning, 6th inst.

On motion of Professor Davis, the Convention then adjourned to meet at 10 A.M. on Monday morning.

THIRD DAY.—MAY 6, 1867.

MORNING SESSION.

PROF. A. STILLÉ, President, in the Chair.

The minutes of the previous session were read and approved.

The Committee on Credentials announced Dr. T. M. Logan, of Sacramento, California, as an authorized delegate from the Faculty of the Toland Medical College of San Francisco.

Professor Gross moved to consider parts of section 4, relating to the branches to be taught in medical colleges.

Professor Hammer moved to suspend the rules for that purpose. Carried.

Professor Gross moved to amend part first, section 4, by inserting the words "Medical Ethics" after the words "Medical Jurisprudence."

Professor Palmer moved the adoption of the amendment. Carried.

Professor Comegys moved the reconsideration of section one.

After suspension of the rules this motion was adopted.

Professor Comegys moved to amend Section 1, by inserting "Elements of Natural Sciences" after the word "Mathematics." Carried.

Professor Hammer moved the adoption of the whole section as amended. Carried.

Section 6 was then considered.

On motion of Professor Donaldson it was laid on the table.

Professor Palmer then introduced the following resolution:

Resolved, That every medical college should immediately adopt some effectual method of ascertaining the actual attendance of students upon its lectures, and other exercises, and at the close of each session of the attendance of the student a certificate, specifying the time and the courses of instruction actually attended, should be given; and such certificate only should be received by other colleges as evidence of such attendance."

The resolution was adopted.

Prof. Davis moved the adoption of all the section as amended. Carried.

Prof. Gross moved to transmit a copy of these sections as adopted by this Convention, certified to by its officers, to the American Medical Association, at its next session.

Prof. Davis then introduced the following resolution:

"*Resolved*, That a committee of five be appointed by the President, whose duty it shall be to present the several propositions adopted by the Convention, to the trustees and faculties of all the medical colleges in this country, and solicit their definite action thereon, with a view to the early and simultaneous practical adoption of the same throughout the whole country. And that

the same committee be authorized to call another convention whenever deemed advisable."

The Chair appointed the following gentlemen that committee: Prof. Davis, of Chicago; Donaldson, of Baltimore; Gross, of Philadelphia; March, of Albany; Blackman, of Cincinnati.

The Chairman then introduced Dr. Vattier, President of the Cincinnati Academy of Medicine, who invited the members of the Convention to be present at the opening of the Academy in the evening.

Prof. March moved to accept the invitation. Carried.

On motion of Prof. Davis, a vote of thanks was returned to the Chairman and Secretary of the Convention for the efficiency with which they had discharged their duties, and to the Faculty of the Ohio Medical College for the use of their hall.

The President returned his thanks to the members of the Convention in a neat and appropriate speech.

Prof. Stevens moved that a formal written thesis on some professional topic shall still be regarded as one of the indispensable requirements for the doctorate.

Remarks were made by Professors Comeygs, Stevens, and Donaldson.

Professor Davis then rose, simply to suggest whether there was not some danger of entering upon the consideration of propositions involving details that might unnecessarily complicate the great leading object for which we have been laboring. Whether the time-honored and universal custom of requiring the medical students to write a thesis should be insisted on or not, would have but little bearing on the great principles involved in the revision of our system of medical education. If the standard of preliminary education which we have here adopted should be carried into effect, it would remove one of the objects for which the writing of a thesis was originally demanded. Yet, he said, it was desirable to retain the practice, if for no other purpose than to encourage every student in the habit of expressing his thoughts on paper. But the great and all important object of this Convention was simply to place the system of medical education in this country upon sound educational principles, by erecting a standard of preparatory education, by increasing the period of study, by adding to the college courses, and by determining a rational order of study. This we have now done, so far as this Convention is concerned, by the harmonious adoption of the five propositions already passed upon. And he earnestly suggested whether we had not better stop here, and devote the remainder of our time to the work of devising the most efficient means to secure the adoption and simultaneous practical execution of the provisions already agreed upon by all the colleges of our country; and leave all minor matters of detail to be determined as time and circumstances should indicate in the future.

Thereupon, on the motion of Professor Hammer, the Convention adjourned subject to the call of the committee.

DEATH FROM CHLOROFORM.—A death during the administration of chloroform took place on March 2d, at the North Staffordshire Infirmary. The patient was a boy aged fifteen, who was about to be operated upon for the removal of necrosed bone from the stump of an amputated thigh. Between two and three drachms of chloroform were used. On *post-mortem* examination the right side of the heart was found loaded with dark-colored blood, and the lungs were highly congested.—*Lancet.*

THE LATE MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

As will be seen, the meeting of the American Medical Association was quite an interesting and profitable one to all those in attendance. The delegates, of whom there was an unusually large number present, evidently came with a determination to work faithfully and harmoniously; and as a consequence a very considerable amount of ground was travelled over, and much satisfaction prevailed as to the general results of the deliberations.

We were hardly prepared for the ominous silence upon the subject of specialties, and are now unexpectedly called upon to congratulate all parties concerned in reference to a happy conclusion, evidently very generally shared, to drop all discussion upon it, at least for the present.

The meeting, although larger than usual, was not well attended by Southern physicians; but this was not, however, to be interpreted as owing to a lack of interest in the welfare of the Association, or of a desire to cultivate those feelings of professional brotherhood which are above party spirit or sectional differences. Dr. Yandell, of Kentucky, in an eloquent appeal on behalf of many of his absent brethren, gave truthful utterance to their sympathies and opinions when he assured the members that there were other reasons for so many still vacant benches than a want of desire to be present. In a word, many of the physicians of the South, in consequence of the war, are much straitened in their finances, and cannot afford even such a temporary respite from their labors as an attendance upon the meeting would involve.

The subjects discussed were so numerous, and very many of them of such importance, that we shall not attempt to review them in detail, but merely allude to them in passing, trusting for a more fitting opportunity in future for such comments as may seem to be called for.

The adoption of the resolutions offered by Prof. C. A. Lee, on the subject of cholera and the utility of quarantine, has committed the Association more fully than heretofore to this great question; and the action

which it has taken will, no doubt, result in placing the doctrine of the communicability of the disease upon that proper and scientific basis which it should have occupied a year ago.

The Convention of Medical Teachers was in every way a success, and the endorsement of its report by the Association was, on the whole, very praiseworthy. In consideration of the step taken, the friends of Medical Education may congratulate themselves that a practical reform is initiated, and that there is a promise, in the virtual permanent organization of the body, of the accomplishment of even better things. But we shall reserve more extended remarks upon this interesting theme for a future occasion.

Female education has thrust its claims upon the attention of the members, and will in time furnish food for a good deal of discussion as to the utility and practicability of a general recognition. Unhappily for the aspirations of the tender sex, the question is destined to lie over for another year, during which time ample opportunity will be given to all concerned to weigh with calmness and deliberation all the arguments *pro* and *con*.

The courtesies which were extended to the members by the profession in Cincinnati were all that could be expected from a city celebrated for the hospitality, wealth, and social culture of its inhabitants. In view of the enjoyment of the guests at the various entertainments, and the appreciation of the kindnesses tendered them, there is not much hope that the expressed opinion of a few that these gatherings are detrimental to the best interests of the Association, will meet with general favor. There is a time for work and a time for recreation; and both should be judiciously blended, in order that each of the annual sessions shall minister to the social as well as professional interests of our brotherhood.

At the end of a notice of an election for examiners in the University of London, occurs the following paragraph, which we would respectfully commend to the attention of Boards of Appointment in the United States:

"Candidates must send in their names to the Registrar, with any attestation of their qualifications which they may think desirable. *It is particularly desired by the Senate that no personal application of any kind be made to its individual members.*"

Our anxiety to furnish our readers with a complete report of the proceedings, at the earliest possible date, has compelled us to delay, for a day or two, the issue of this number; and in order to give ourselves sufficient space for the accomplishment of our purpose, we have been compelled to defer several interesting communications, which we would otherwise have been enabled to insert.

Reviews.

Infantile Paralysis and its Attendant Deformities. By Charles Fayette Taylor, M.D., Resident Surgeon N. Y. Orthopœdic Dispensary, Author of Mechanical Treatment, Angular Curvature of Spine, etc. Philadelphia, J. B. Lippincott & Co., 1867. 12mo. Pp. 119.

For a number of years Dr. Taylor has been giving his entire thoughts and energies to the development of a more rational and successful method of treatment, for a certain class of deformities, than is commonly practised even by the most intelligent physicians. His labors in this department, though they have not been unattended by a share of the oppositions and despisings with which the human race usually greet all schemes designed for its amelioration, have certainly been crowned with a success that must be most gratifying, not only to Dr. Taylor and his immediate coadjutors, but also to all progressive minds in the profession everywhere. The theory of the movement cure is founded on the best of common sense, and its practice, though requiring greater patience and skill than the administration of pills and boluses, is yet much more successful, as it is far more philosophical.

In this little volume, Dr. Taylor treats of a subject of far greater importance than the majority of practitioners may be willing to accord to it, but those who have been so situated as to have had opportunity for seeing these diseases at their genesis, and in their resulting deformities, will surely admit the necessity of a clearer understanding of this subject among medical men.

The main ideas of the work are admirably summed up by the author in the following propositions:

1. Infantile Paralysis is an arrest of negative development from some unknown cause. 2. The characteristics of this form of paralysis suggest a peripheric blight, rather than a loss of central nerve power. 3. With diminished nutrition, temperature, and muscular power, there is also diminished muscular irritability; and there is no such thing as involuntary or reflex contraction in infantile paralysis. 4. The shortening of certain muscles is not a necessary consequence of infantile paralysis; and when it does occur, it is simply the adaptation of their length to the position they happen to be in. 5. It is entirely accidental which muscles become shortened, whether flexors or extensors. 6. Hence deformities are not a necessary consequence of infantile paralysis, and when they are allowed to occur, the process of recovery is arrested. 7. When deformities have already formed, they should be treated for an ultimate end, viz. to bring the patient back to the place from which he should not have been allowed to diverge, when the treatment for his paralysis should begin. 8. Hence, tenotomy and mechanical appliances are only means to an end, the first steps of a course of treatment having in view the restoration of the muscular power. 9. The most natural means for this purpose is the supply of local heat, involving increased local circulation, together with local exercise corresponding with the position and ability of the part exercised. 10. The element of time must also be taken into consideration.

These propositions contain the leading principles of the author's philosophy, and that they will stand the test of experience we have no doubt. His theory in regard to the pathology of infantile paralysis is very clearly put in the following sentence:

"If we can conceive of a general constringing of the capillary vessels, and a shutting off of the capillary circulation, with such a physical condition as would re-

sult if the limb had been for a long time tightly bandaged, we should form a very good idea of the actual condition in infantile paralysis."

It is our belief that not only infantile paralysis but also many of the so-called hysterical paralyses of adults may be accounted for on precisely the same theory and demand the same treatment.

The special methods on which Dr. Taylor relies to increase the local circulation are, "the supply of local heat and local exercise, corresponding with the position and ability of the part exercised." For carrying out of the latter indication, he relies mainly on his mechanical appliances.

These, so far as they go, are admirable, but the author makes no mention of *rubbing* or of *electricity*, both of which have for a long time been used with success in the same class of diseases.

Although these agents have been mostly in the hands of charlatans, who have labored in blindness and ignorance, and oftentimes with detriment to the health as well as purses of their victims, they have yet in many instances stumbled upon the most brilliant success.

Electricians and rubbing doctors, whether they are aware of it or not, perform their cures in the same way as Dr. Taylor; namely, by increasing the local circulation.

Dr. Taylor says that the American people are weak in bodily vigor, and that infantile paralysis is most common among the rich. With all deference to his large experience and careful observation, we feel compelled to differ from him on this subject. It is singular that in this, the only passage of his book where Dr. Taylor shows any respect for popular prejudices, he seems to be entirely at fault. Probably many in the profession will give to this statement unquestioning assent, but we feel confident that if Dr. Taylor will take the pains to investigate this subject, with the same courage and independence that he has advocated the claims of the "Movement Cure," he will become convinced that nowhere can be found a nobler average of physical and intellectual manhood than among the native population of America: nay more, that the women of our better classes, even in our large cities, are measurably healthy as well as beautiful, and that infantile paralysis is as prevalent, or more so, among the poor and oppressed as among the cultivated and high born.

But putting aside these collateral questions, which at best must remain matters of opinion, we earnestly commend this work to the careful attention of all in the profession who feel the need of a more rational system of treatment in paralysis than has hitherto found favor.

Life in Scotland.—There are in Scotland 216,723 houses of only one apartment, a large number of which "accommodate" eight or ten persons each. Nearly 8,000 of these dwellings have no windows! One million of people, nearly a third of the entire population, live in these one-roomed houses. Edinburgh has fifteen hundred one-roomed houses, and Glasgow over twenty-two hundred. And yet Scotland is regarded as a part of the civilized world.—*Pacific Medical and Surgical Journal.*

A New Medical Society in Paris.—A new society has just been founded in Paris in order to study, *seriatim*, the different agents of the materia medica hitherto in use.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 13, 1867.

Dr. H. B. Sands, President, in the Chair.

THE OPHTHALMOSCOPE AND RENAL DISEASE.

Dr. Noyes exhibited an eye which had been extirpated a week ago last Sunday, from a lady 40 years of age, unmarried; and who had regarded herself as being in good health, and who had lost this eye twenty years ago by severe internal inflammation. There was disclosed, on examination of the organ, a large staphyloma of the ciliary region of the sclerotic; there was cataract, the lens oscillating back and forth, and there was no perception of light. She had not suffered any inconvenience from the eye except a sense of weariness, which would be felt sooner than in other parts of the body. Ten days previous to the operation, she living out of town, had come to the city to attend the wedding of a relative, and did not in consequence retire as early as usual. On the following morning she noticed, for the first time, that the sight of the previously sound eye was very much impaired. She had applied to several gentlemen, who had expressed the opinion that the trouble was merely sympathetic.

When she afterwards called on Dr. Noyes for advice, that gentleman was surprised to find on examination of the eye last affected, strong evidences of the existence of Bright's disease in the shape of extensive fatty degeneration, and abundant ecchymosis of the retina. An inquiry into the state of her general health failed to elicit anything satisfactory, notwithstanding she was a very intelligent lady, and was observant of symptoms. She stated that both her parents and great-uncle died of heart disease. An examination of her heart was made, and although it was somewhat imperfect, the doctor felt pretty sure that hypertrophy existed, dependent upon what cause he could not determine. A careful examination of the urine resulted negatively, the specific gravity was 1,024, and there were present a few renal epithelial scales undergoing fatty degeneration, and some crystals of the oxalate of lime. He advised the removal of the diseased eye merely to get rid of an annoyance, not viewing it, in itself, as a source of trouble. Previous to the operation, first chloroform and then ether was administered. There was considerable hæmorrhage, but this was by no means as annoying as a peculiar irregularity of the heart's action, which kept up for the first twenty-four hours after the operation.

Since that time he had carefully watched the case, and had satisfied himself of the existence of mitral insufficiency. Examination of the urine afterwards, discovered one or two appearances that the doctor felt assured were casts, as well as an abundance of vaginal and renal epithelium. He was therefore pretty strongly convinced that this was a case of chronic disease of the kidney, in which hypertrophy of the heart had supervened, and in which the first symptom appearing of any diagnostic value, was to be found in the change in the retina; that change unrecognised, but occurring during one night, culminating in an attack of neuro-retinitis, which greatly impaired the vision of an eye apparently previously unaffected.

The specimen removed was suspended in a glass cell in preservative fluid, and showed the retina completely detached by fatty degeneration between it and the choroid. The lens was free and floating about in the anterior chamber.

Dr. Sands was not inclined to think that the ophthal-

moscope could always decide as to the existence of renal disease when no other symptoms of that trouble were present. He had met with two instances during the past year in which, if he had relied entirely upon an ophthalmoscopic examination, he would have said renal disease unquestionably existed. There was, however, a disappointment in not finding any other evidences of kidney trouble.

Dr. Noyes remarked that in the present state of the question one or two examinations of the urine should not be considered sufficient to decide against the existence of Bright's disease when the ophthalmoscope had decided for it.

Dr. Newman referred to two cases of Bright's disease, the diagnosis of which was first made out by the ophthalmoscope in the hands of Dr. Althof, of New York. In both instances repeated examinations of the urine were made, for a long time without avail, when finally casts were discovered with the other symptoms of the disease. Both patients afterwards died, and the diagnosis was unequivocally confirmed by a *post-mortem* examination.

Dr. Noyes alluded to a case of renal disease which the ophthalmoscope had at first pointed out to be such, but in which no other evidences of the correctness of the diagnosis were afterwards made out, save in the diminution of the quantity of urea excreted to two-fifths of its normal amount.

Dr. Flint believed that the fact was well established, that there might be a temporary disappearance of casts and albumen for a considerable time, and yet the patient be suffering from advanced Bright's kidney.

Dr. Noyes stated that a case had occurred to him within the last week, which bore strongly upon the general question under discussion. A young man of fine, vigorous appearance, who had never suffered from ill health, except that occasioned by a capricious appetite, and more or less headache, came to his office to be treated for strabismus. On using the ophthalmoscope, however, the characteristic changes of Morbus Brightii were seen upon the retina, and an examination of the urine afterwards disclosed casts and albumen.

Dr. Flint exhibited an intestinal calculus which had been found in the intestinal canal just above the cæcum, having evidently existed in that locality for the long period of twenty years.

GRADUAL PERITONITIS FOLLOWING PERFORATION OF APPENDIX.

He next presented another specimen which had been taken from the body of a patient attended by Dr. Chas. D. Smith.

A young man, aged 18, was attacked, on the 22d of last December, with some pain and soreness in the abdomen, which was referred to the right iliac region. It increased, but he did not take to his bed until the 26th, when he was seen by his attending physician. He then presented symptoms pointing strongly towards peritonitis, but they were not sufficient to found a positive diagnosis upon. On the day following, these symptoms were well declared, and in the evening Dr. Flint was called in consultation. There was then rigidity of the abdominal walls, moderate tympanitis, tenderness on pressure, pulse 116, and the pupils were somewhat contracted from the opium which had been administered. The disease progressed, and on the following day the tympanitis was more marked, the pulse more frequent, and death finally ensued on the 28th.

The *post-mortem* examination gave evidences of general peritonitis. There was a certain amount of muddy liquid in the peritoneal cavity, recent lymph agglutinated the intestines, while the whole serous membrane was covered with an arborescent redness. The vermiform appendix was found adherent to the abdominal walls, and had a perforation about its centre. Within the cavity of this latter organ were two solid bodies, apparently fœcal in character, one of which was somewhat oval, the other more rounded.

The development of the peritonitis was so gradual that it was at first supposed (contrary to what was afterwards shown) that the peritonitis was at first idiopathic, and, of course, independent of the perforation. The treatment was by opiates freely and persistently administered.

CARDIAC DISEASE WITH PULMONARY APOPLEXY.

Dr. Draper presented a specimen of heart disease, complicated with pulmonary apoplexy. He gave the following history of the case:

The patient, a seaman, 33 years of age, was admitted to the New York Hospital on the 4th of this month. He had always been a man of temperate habits. He left Mobile twelve days before admission, in the enjoyment (as he said) of perfect health. When two days out, he took a chill, followed by pain in the left hypochondrium, and considerable difficulty in breathing and cough. He took to his bed, and two days after the chill he had some swelling of the feet, and was unable to resume his duties during the passage. When admitted to the hospital he was suffering from extreme dyspnœa, and the action of the heart was so tumultuous that the house physician was unable to detect any cardiac lesion; he however observed that the area of præcordial dulness was increased. On examining the lungs he noticed a marked resonance on percussions over the whole chest, with puerile respiration, and some coarse rhonchi. He applied dry cups and sinapisms, and administered stimulants. On the following day, the action of the heart was sufficiently regular to enable him to appreciate the abnormal condition. The area of dulness was considerably increased, though the apex was not as much displaced as might be supposed, considering the amount of hypertrophy which was present. The apex beat in the proper perpendicular, but in the sixth intercostal space. At the base of the organ there was a double murmur; the systolic was short and rough, the diastolic prolonged, soft, and higher pitched. Both of these were noticed at the base of the organ. On examining the chest, Dr. Draper found a different condition of things from that noticed by Dr. Seguin; there was dulness on percussion posteriorly, and so feeble was the respiration that he was inclined to think that there was pleuritic or pulmonary congestion; he was unable positively to determine which. The man's condition was still very critical; the dyspnœa was considerable; he could not lie down in bed, and suffered considerably from præcordial distress. He continued in this condition for four days, when he died from exhaustion.

On *post-mortem* examination made a few hours after death, the lesions found were as follows: The aorta was considerably distended just beyond the aortic valves. The aortic valves were insufficient, the left ventricle was considerably distended, and the mitral valves were also insufficient. Both sides of the heart were considerably distended with blood. On further examination, the left pleural cavity was nearly filled with turbid serum; and the left lung, which was consolidated in consequence of effusion, was found also to be the seat, along its marginal portions, of considerable interstitial apoplexy. The interesting point appeared to him to be the short period during which the patient suffered from heart symptoms. He had stated that he had never noticed any cardiac symptoms whatsoever until

after he had left Mobile. It was very evident, however, that it had existed for a considerable period, as large atheromatous plates lined the aorta for a considerable distance above the aortic valves. As the result of his observation, he remarked that the lesions of the aortic valves were those in which the patient suffered least, and supposed the reason was, that the point was one most distant from the general venous circulation. Here, as in most cases of disease of the aortic valves, the left ventricle had undergone very considerable distension, and until this distension caused insufficiency of the mitral valves, patients never suffer seriously from pulmonary congestion. When, however, this does occur, pulmonary congestion is inevitable. He thought it was very unusual to see that amount of lesion when no cardiac symptoms manifested themselves until so short a period before death. In conclusion, he remarked that there were two anomalies, one in the artery, the right carotid opening in common with the innominata, and one in the vein; there being two pulmonary valves instead of three.

DEATH FROM CHLOROFORM AT BELLEVUE HOSPITAL.

Dr. F. H. Hamilton presented the severed head of a female, for the purpose of exhibiting the results of an unfinished operation, she having met her death from chloroform. The patient was an Irishwoman, 36 years of age, who had her nose bitten off, January 1, in a brawl with a negro who it was understood was her paramour. She was admitted to the Bellevue Hospital on the same day, and on the day following was seen by Dr. H. He found that about an inch and a quarter of the end of the nose was gone, as well as the septum and columna nasi, with perhaps four-fifths of the alæ nasi. At a consultation held on the seventh day it was decided to operate for the restoration of the nose immediately.

The first operation consisted in freshening (excising) the margins of the wound upon the nose in the usual manner, and then covering in the end of the nose with a piece of integument taken from the forehead. This frontal flap was taken from the centre of the forehead, and was so prolonged upwards in the median line as to form, when brought down to its place, a columna. The pedicle, or "bridge," supporting the flap, was much wider than other operators have generally seen fit to make it, so wide indeed as to include a portion of the eyebrows. This gives greater security to the flap; but the width would be objectionable were it not that it was intended to cut this pedicle eventually, near the end of the nose, and lay it back in its original situation.

The flap thus made was turned upon itself, and made fast by side sutures.

A few days later, when adhesion had taken place through nearly all of the resected margin, Dr. Hamilton freshened the central, tongue-like prolongation, and fastening it below, constructed the columna. This united well, and "you are able," said Dr. Hamilton, "in the specimen which I present to you, to see the result at the end of one month from the date of the first operation."

It was his intention now to cut the pedicle, and carry it back to its original place, a method of procedure which he has, up to this time, adopted in four cases, and which he thought might be regarded, in its application to certain cases, as an improvement upon the usual practice. No doubt it will be better to leave the pedicle upon the nose in all cases in which the bridge of the nose is depressed, and needs elevation to give it proportion, but in cases like this he thought his own procedure ought to be preferred. Dr. Hamilton did not pretend to say that the operation may not have been made in this manner by other surgeons, only he thought it was not the usual practice.

In reference to the mode of death in this case Dr. Hamilton remarked, that the chloroform and ether were administered by a very intelligent house surgeon. The administration of the chloroform was in his absence, but this circumstance was accidental. The patient was brought into the room at ten o'clock, and placed upon the table, Dr. Hamilton having previously directed that a little chloroform should at first be given, to be followed by ether. The chloroform was poured upon an open napkin, and held some distance from the face. After a short time ether was substituted for the chloroform. Both the chloroform and the ether were manufactured by Squibb, and were chemically pure. Dr. H., on entering the room, found her talking loudly, and throwing her arms about. She was then taking ether from a cone. The noise she occasioned was too great to permit him to speak to the students upon the operation, and he accordingly waited about five minutes for it to subside. She then was quiet, and breathing naturally. Dr. H. then stepped to the other side of the table to look to the transfer of instruments to the opposite side of the patient, then turned again to the table, and back to the patient, when he discovered that she had ceased to breathe. It is worthy of note that she was at that time pallid, and that there was no appearance of asphyxia. It was Dr. Hamilton's belief that the heart had then ceased its pulsations. He could not feel any pulsation at the wrist, but did not stop to ascertain whether the carotid beat. He immediately commenced artificial respiration; turning her first upon the left side, and then upon her back, in which latter position the hand was pressed against the ensiform cartilage. In three-quarters of a minute after this there was a full inspiration, and the patient was thought to be comparatively safe. There was, however, the same long interval between this and the next inspiration. It is perhaps proper to say at this moment that the tongue had previously been pulled out, and held in that position by a tenaculum. The battery was next ordered and applied, perhaps at the end of eight minutes (the efforts at artificial respiration being in the meantime kept up). The battery was applied, with one pole over the heart, on the left side, and one over the region of the diaphragm, upon the right side. This was done without any positive knowledge as to what had been the usual practice in the application of the battery in similar cases. He had, however, noticed since, that it has been advised to apply one pole in the course of the phrenic nerve somewhere on the neck, and the other to the region of the diaphragm; the authorities to which he had referred affirming that the battery under these circumstances induces a spasm of the diaphragm, and a consequent sudden inspiration. As it was applied in this instance no effect was produced. The battery was then removed, and the patient was turned upon her left side, when one or two short inspirations followed the procedure, and then respiration failed altogether. It was not until the respiration had entirely ceased that the lips became purple. Laryngotomy was next resorted to, and a further attempt at artificial respiration made for three-quarters of an hour longer, when the patient was resigned as dead. Although the position for inducing artificial respiration was not the one recommended by Marshall Hall, still Dr. H. thought in this case, the woman being large and unwieldy, it evidently answered every purpose. An autopsy was made on the following day, but nothing was found to furnish any explanation of her death.

Dr. Hamilton, in conclusion, wished to place on record an account of several other cases of a similar operation

to the one intended to have been made, all of which had terminated favorably.

1. Sept. 22, 1855, in presence of Dr. Boardman, of Buffalo, and others, I operated on Dennis Davy, Irish, æt. 30, from Medina, Orleans co., N. Y. His nose had been bitten off, seven days before, by a man in a fight. I did not use chloroform. Having freshened the edges of the wound, I dissected up a piece of integument from the forehead, and transplanted it to the nose. It united well. Thirteen days later I cut the pedicle, and restored it to its original position. The result was completely satisfactory.

2. July 3, 1857, I operated in a similar manner upon Dr. S. Ward, of Silver Creek, Cattaraugus co., N. Y., for an epithelioma, on the left ala of the nose. The portion of nose and face removed was about one and one-half inch in diameter. I took the integument from the forehead. The success was perfect.

3. March 30, 1852, I operated in the same manner upon Pardon Davis, of Brockport, N. Y., for an epithelioma of the side of the nose and eyelid, in presence of Drs. Clark, Thatcher, Carpenter, Wood, &c., of Brockport. Mr. Davis was sixty-four years old. The skin united very promptly, but the disease eventually returned in the bone.

4. I made the same operation for an epithelioma on the side of the nose, near the eye, in the case of Parmele Parmentis, of Chatauque co., N. Y. She was then about twenty-six years old. The result was a perfect success.

Dr. Post remarked that Dr. Hamilton's method of treating the flap was not unusual, as that gentleman had intimated, but was one generally employed by surgeons. He thought that the safety of the flap in all these cases depended more upon a wide pedicle and an easy twist than anything else.

Dr. Krackowizer thought it a better plan not to transplant the flap from the forehead, but from a little outside the freshened edges. He did this in one case, and would have been successful had he not endeavored in the first operation also to form the columna. He agreed with Dr. Hamilton in the opinion that his method of treating the flap was unusual, if not entirely new.

Dr. Noyes had seen a rhinoplastic operation performed, the flap being taken from the forehead, with a good result. He also referred to one that was made by Maissonneuve, where the flap was taken from the forehead. In this case the return circulation being painful in consequence of the congestion caused in the flap, and the part being likewise of an unnatural reddened hue, a leech was applied every twenty-four hours. While the leech was on the normal hue returned, and the flap eventually survived.

Dr. Hamilton referred to a cut of a case of his published in the fourth volume of the Buffalo Medical Journal, which represented a method which he had employed of transplanting skin from the palm, radial margin, and back of the hand, to restore the nose of a man who had lost much of his nose, and was otherwise badly disfigured by a burn of the face. In that instant, by demand of the patient, the flap was separated at the end of forty-eight hours. The result was that about three-quarters of the flap sloughed, but there was, however, a very satisfactory nose left.

Dr. Sands was much interested in the description of the symptoms of the case of death by chloroform, because he thought that it tended to confirm the growing impression that such a result was due to the failure of the heart rather than of the lungs. He then related the case of a patient of Dr. Da Costa, to whom he administered a second time chloroform, for some manipulation about the elbow-joint. At the first administration everything went off well, but on the second occasion the pulse began to grow suddenly feeble, and finally ceased beating altogether. In that instance he had noticed that the stoppage of the pulse preceded that of the respiration. Marshall Hall's method was then resorted to, and the patient was eventually, with much difficulty, resuscitated. He had witnessed death in two cases from ether, both of which occurred at the N. Y. Hospital. In the first case a man was brought into the institution having accidentally cut his throat while engaged in pruning trees. The right carotid artery was wounded, and there was left a large false aneurism. The consultation decided it to be best to cut down through the swelling, and secure the ends of the wounded vessel. During the administration of the ether the doctor had his hands upon the pulse. It ceased suddenly before the respiration did. In this instance there were some signs of life. Subsequently the patient breathed again, and the pulse began to beat, so that the operation was proceeded with; but these favorable symptoms existed for only half a minute when the pulse ceased, followed by an arrest of the respiration. In the other case the patient had a cancerous tumor of the antrum, for which an operation for removal was to be attempted. The ether was administered, but the first incision was only made; a very little blood passed down the throat, and the patient died instantly by, as then supposed, syncope.

Dr. Post remarked that a similar case had occurred at Saint Luke's Hospital. The operation was for the removal of a tumor of the neck, and death occurred suddenly while the patient was under the influence of ether.

Dr. Noyes referred to a similar case of death from ether, in which galvanism was resorted to by acupuncture needles passed through to the heart.

Dr. Hamilton stated that death had occurred, at Bellevue, in two cases besides his own, after giving chloroform, and in one after giving ether. In the latter instance there was found, after death, to be a tumor in the cerebellum. He had heard, incidentally, of two others in this city, both of which occurred in private practice, one in the practice of Dr. O'Reilly, the other in the practice of Dr. Van Buren.

Dr. Cutter referred to a case that had occurred to him. One part of chloroform and two of ether were given to the patient by a cadet in the Newark Hospital. The proposed operation was one for re-amputation, and shortly after it was commenced the patient ceased to breathe. Marshall Hall's method was resorted to, and respiration was re-established; chloroform was again given, when the patient almost immediately died. The anæsthetics were given in a paper funnel, and the fatal result was probably in no small degree due to the want of a proper supply of air.

Dr. Sands referred in this connexion to the case reported by Dr. Briddon of a child who, while under the influence of chloroform, vomited, and a portion of fried liver, which she had eaten shortly before, lodged in the larynx, causing immediate suffocation.

Dr. Cutter then presented a specimen of diseased humerus, which he had exsected. The history of the case he then read from the January number of the *American Journal of Medical Sciences*, for 1866.

Dr. Hamilton desired to call attention to one or two points. In the first place the case was not one of removal of the entire shaft of the humerus in a single operation; an important portion, namely, the upper one-fourth, having been previously exsected. It was in reality then only a removal of the lower three-fourths of the bone. In the second place, he thought that the operation was unnecessary, and he furthermore thought

it our duty to make it so understood, that it might not stand as a precedent for others. The sequestrum was entirely separated from the involucrum, and could have been removed without removing the involucrum. If this had been done the patient would have had a more useful limb than at present, as the involucrum was evidently strong and able to support the limb tolerably well. And again the joint end of the bone was not dead; death having only extended to the central portion of the shaft, and there was no occasion, therefore, for removing the entire joint. He was of the opinion that in case the dead bone could not have been removed, the next best thing would have been amputation. It was easy then to infer that he was not an unqualified advocate for resection. In fact he stated that he believed, with that distinguished surgeon, Dr. March, of Albany, that too many of those operations had been done already. He doubted whether the man had a useful limb after all, and was of the opinion that when the novelty of the apparatus which he was using wore away, he would ask to have the arm amputated. Without the apparatus the arm was useless. The apparatus would require constant repair. Furthermore, the experience of the "left-armed soldiers" who had been training themselves in the use of the pen, showed that the entire loss of even the right arm might in a great measure be supplied. The time had not yet arrived for a fair verdict upon those operations.

Dr. Cutter remarked that the case was not reported as removal of the entire humerus in one operation, as the first operation of removal of the head and upper part of the shaft was credited to another surgeon. The propriety of the operation was urged upon the ground that there were numerous openings all around the arm leading to dead bone, that the necrotic tissue was everywhere felt, that the patient's health was suffering in consequence, and furthermore it was impossible to diagnosticate precisely the relation of the dead to the living. He further said that the condition of the soft tissues around the joint was such as to lead him to suspect irreparable disease of that part. He did not think that the involucrum would ever have become sufficiently strong to have made a good arm. The patient seemed perfectly satisfied with the result of the operation, and would not part with what arm was left him for any consideration.

Dr. Post stated that he had seen the patient, and was satisfied that the operation was, under the circumstances, an eminently proper one.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, April 1, 1867.

Dr. Samuel T. Hubbard, President, in the Chair.

CHOLERA AND CONGESTIVE FEVER—THEIR ANALOGIES.

(Continued from page 114.)

Dr. Edmund Fowler next read a paper upon "Cholera and Congestive Fever, their leading Characteristics, Relations, and Analogies." Having premised that he had not systematized the subject, but should speak discursively, and after an argument to prove that the premonitory diarrhœa should be considered properly a stage of cholera, Dr. F. stated the characteristics of this disease to be, "Initiative diarrhœa, violent purging, vomiting, cramps, præcordial oppression, restlessness; a quick, rapid, thready, distinctive pulse; cold surface; cold, profuse perspiration; wrinkled, sodden state of the skin on the extremities; intense thirst; a sense of burning heat in the epigastric region, and in the bowels; a rapid sinking of the powers of life, collapse, and death, or reaction and consecutive fever. In the algid form of congestive fever, in the abdominal species, we have vomiting; serous purging, which is at times flocculent; præcordial oppression, great restlessness, intense thirst, a burning heat in the epigastric region and bowels, cold skin; often cold, profuse perspiration; a small, quick, thready pulse; blueness of the lips, collapse, and death; or reaction, and not unfrequently consecutive fever, though this more often attends remittent disease. This outline presents not essentially dissimilar characteristics." The two diseases have many lesions of function, of tissue, of blood, analogous, if not identical. Again, they are alike in what may be called the lesions of expression, which, although they furnish no facts for the dissecting-knife, are as much a part of the history of disease as changes in the tissue. The language which addresses us from the rapid grouping of all the features of a case, though hard to translate in scientific terms, is often unmistakable in its indications, and may determine our happiest decisions.

In cholera, all observation tends to show that early and important changes occur in the blood, that its lesions precede and accompany the profound changes in the mucous, serous, and glandular tissues. Both its own condition and its relations to the system through the circulation are rendered abnormal. It becomes thick, ropy, and adhesive, and it stagnates in the capillaries and veins, the arteries being left nearly empty. In congestive fever one of the first things to be observed in the blood is its thickened condition. It is sometimes oily, and gathered into large, well-formed globules; at other times it is adhesive, and cannot be made to escape from the vessel. In extreme cases of congestion, proving fatal in from ten to eighteen hours, it is perfectly gelatinized in the veins. In these cases, if a vein be laid open to the extent of twelve or eighteen lines, so as completely to expose the blood, this will be found of the consistence of partially coagulated albumen, dry, adhesive, and retaining its cylindrical form after being carefully removed from the vein. I speak now of what I have witnessed while yet the patient was able to walk from his bath to the bed, where he expired within ten minutes after I had exposed the blood to view. The congestion in this case was in the chest and abdomen, the intellect remaining clear and undisturbed. This patient was a child of eight years, who had been stricken down with a malignant chill two hours before. There was no vomiting, purging, or excessive perspiration. The case was not unlike many described by Mr. Orton, in the second visitation of the cholera in India, in 1818, in which vomiting, purging, and spasm were in a great measure absent. A characteristic phenomenon of congestive fever is that the limbs in some instances, the body, neck, and face, very generally, are more plump than in health. In these cases the congestion is very profound, and attended with slight, if any, serous discharges from the bowels. The explanation is probably that the blood-plasma, exosmosed into the subcutaneous cellular tissue, becomes there partially coagulated by a like change with that seen in the veins, and so remains fixed. It is noteworthy that the spissitude of the blood, so apparently similar in the two diseases under consideration, and rarely, if ever, found in any others, should be followed by such opposing dispositions of the blood-plasma. In those cases of congestive fever, where we have abundant serous discharges, followed by sodden, wrinkled skin on the hands and feet, its parallelism with cholera is, of course, more evident.

The history of congestive fever was next discussed, especially as it had appeared in the valley of the Mississippi, and on the borders of the Gulf of Mexico

where it was so prevalent and so fatal. The conclusion was reached that prior to the year 1834, true congestive fever was unknown there. Not that it was unusual to find congestion complicating fevers and increasing their danger; but that the congestion which gave distinctive character to the fever which first startled the people of that region in 1834, culminating in 1843, was attended with phenomena so exceptional as to demand a new name. Watchful of the influence of epidemic cholera in modifying disease, even in sections where no cases of the epidemic had occurred, physicians could not but remark the resemblance between the known symptoms of that disease and those of the new type of fever. Though the assemblage of symptoms characterizing congestive intermittent is no less marked than that of cholera, its graphic description is less easy, because of the varying seat of the congestion. But in all cases, we observe that peculiar expression seen only, Dr. F. believed, where the blood parts with its plasma, and its remaining elements take on the changes that occur only in these two diseases. An important differential fact between simple congestion and algid congestion is to be seen in the effect of venesection. In the former, blood will flow quite freely from the opened vein, and if sufficient be drawn, the pulse at the wrist will become fuller, softer, and less frequent, while the patient experiences a feeling of relief. In the latter, even a small abstraction of blood is immediately followed by increased restlessness, intenser thirst, a sense of impending death, increased cyanosis of the skin, and a more rapid, thready pulse. In the first case, the temperature of the surface is increased by venesection; in the second, it is diminished. Practically, and as a basis of classification, these conditions are as important as the lesions shown at *post-mortem*. Again, many cases of congestive intermittent present no chilly sensation. The patient is dull, disposed to sleep, complains of a feeling of "tired aching," but is not conscious of a chill. The skin is cool, while he says he is burning up inside. Then, in the best defined cases, though emesis is almost constant, no bile is vomited, but a large amount of muco-serous fluid. Another matter of great moment, which appears to have been overlooked by writers, is the profound change in the nutrition of the system, following even a single malignant paroxysm. The system becomes cachectic; the skin is pale and chalky, and the face wears a look of despair. After a severe case, continued far into the inflammatory stage, not less than three years will be required to restore the normal tone of the system. Even the traces left by cholera may be effaced more easily. Both cholera and congestive fever appear to have been most fatal, and to have resembled each other most closely, in cretaceous districts.

When the miasm of yellow fever swept over the Gulf States in 1853, a new impression was given to the febrile diseases of that region. Now congestive chills are rarely seen there, and since the above date these States, except on the coast, have shown no signs of choleraic influence. As an illustration of the moulding power of epidemics, it has been noted on two or three separate occasions, in New Orleans, that when cholera and yellow fever have prevailed together, cases of the former have shown the genuine black vomit in the stomach at *post-mortem*, while the cadaver of yellow fever has exhibited the muscular contractions characteristic of cholera.

Reviewing the strong analogies between cholera and congestive fever, and remembering that it originated in a locality reeking with miasma, may we not deem cholera a fever also? a fever of a single paroxysm, with phenomena as well marked as those of the other affections classified under this head? Some of the best minds in the profession are of this opinion.

The essay concluded somewhat abruptly, Dr. F. stating that time failed him to speak, as was his purpose, of the analogous states of the capillary circulation in the two diseases. He wished to acknowledge his indebtedness to Dr. Drake for many facts and suggestions.

The paper was accepted, but the lateness of the hour precluded any discussion upon it.

Dr. Downs presented a specimen of a fœtus expelled, with the membranes intact, after a considerable amount of hæmorrhage consequent upon a fall. Dr. Peaslee and others were of opinion that the case was one of placenta prævia.

Adjourned.

EAST RIVER MEDICAL ASSOCIATION.

Stated Meeting, April 2, 1867.

Dr. V. Morse, President, in the Chair.

SPASM OF THE GLOTTIS.

Dr. Newman read a paper on the above subject. He claimed that this disease generally attacks children from the fourth to the twelfth month. Before this the health of the infant may be perfect, unless we except a certain catching of the breath when crying, for which passion gets the credit. After awhile the child becomes uneasy and restless, the head hot, the respiration difficult, which symptom may terminate in asphyxia. The disease mostly occurs during the night, being only occasionally preceded by a slight cough. The infant, after sleeping quietly for some hours, suddenly awakes in great terror, utters a piercing shriek, immediately followed by suffocation; sometimes, and indeed most usually, suffocation commences, and the shriek is only heard when respiration is re-established. This shriek bears some resemblance to that which accompanies croup or hooping-cough, but is more acute and piercing. It has a tone of its own, easily recognised when once heard. The surface is either of a bluish-red or quite discolored; the eyes are prominent and fixed, the nostrils extended, the limbs contracted and cold; the pulse, small, hard, and frequent; there are sometimes violent convulsions present, with relaxed sphincters. Should this condition continue beyond two minutes, death is likely to end suffering by asphyxia or apoplexy. On the other hand, after the respiration is restored, convulsions, strabismus, and stiffness of the limbs still continue. Sometimes all the symptoms disappear immediately, leaving the child pale and fatigued, but breathing freely, and soon falling into a gentle, refreshing slumber. At other times, and mostly when the attack is preceded by a cough, the young patient is again seized with a convulsive cough, like that of women in violent hysterical fits.

However, then, the fit may terminate, the child is soon restored to health, but not to immunity from new and gradually more frequent attacks. At first these only occur in the night and without any apparent cause, but before long they encroach upon the day, being induced by screaming, passion, laughing, running, or eating; in fact, there may be twenty attacks in twenty-four hours. In some fortunate cases, the fits are at a greater distance, they lose their intensity gradually, and disappear after lasting several months, or sometimes years; yet there always remains a predisposition to fatal relapse.

Spasm of the Glottis may occur, and has been observed in children with the best constitution and in full health; but it is mostly common among weak, scrofulous, and rickety children, dentition, gastro-muco intestinal irritation, greatly contributing to the production of the disease.

Among the special causes may be enumerated:

1st. Inflammation of the brain and its membranes.

2d. Alteration of the lymphatic ganglia of the neck.

3d. Hypertrophy of the thymus gland.

4th. Inflammation of the cervical portion of the medulla.

At the commencement of meningitis children frequently have convulsions; when they scream or cough, they suddenly turn blue, the limbs become stiff, the body and head are thrown backwards, respiration is suspended, and when restored its return is ushered in by a piercing shriek; these symptoms increase in frequency and violence with the encephalic affection.

Case 1.—*December* 28, 1865.—Was called during the night to see a child six months old, whom he found in a comatose state: the occiput was burning, the face pale, the skin hot and dry, pulse normal; the pupils exhibited no peculiar abnormality, the tongue white, urine scanty, the respiration free, the head thrown back. Its screams led him at first to suppose the child was suffering from colic, but the abdomen was soft and free from pain. When forced to swallow, the stomach would immediately reject its contents. The child had had several convulsions during the day; but up to this period had enjoyed the best of health. The parents were healthy and robust. His diagnosis was encephalic inflammation. Ordered calome lpurges, leeches, cold to the head, hot foot-baths, and frictions of croton oil to the nape of the neck.

December 29.—The calomel had operated freely, but without improving the condition; ordered more leeches, with iodide of potass.

December 30.—Violent convulsions, respiration suspended, the face blue, the head thrown violently backwards; had lost all hopes, when a violent shriek terminated the spasm, and in a few minutes the child fell into a quiet sleep. Repeated the calomel and iodide with the addition of one-sixteenth of a grain of the extract of belladonna.

December 31.—Convulsions intense, but during intervals the child appeared more composed; the fits of suffocation came on several times during the day and night.

January 1, 1867.—Convulsions less frequent, and not so violent; had but two attacks of suffocation, takes the breast readily, skin moist, pulse soft, bowels free. Continued the iodide of potass and belladonna.

January 2.—Convulsions nearly ceased, and only one fit of suffocation came on during the twenty-four hours.

January 3.—All the symptoms have disappeared; the same treatment continued until the 9th, when he ordered cod-liver oil, and the child slowly returned to usual health.

The symptoms in this case were, in his opinion, due to Spasm of the Glottis, caused by encephalic inflammation.

Inflammation of the cervical portion of the medulla may give rise to spasm of the glottis.

The late Dr. John Corrigan, of Dublin, among others, relates the following case:

Case 2.—A child four months old, who had always been in good health, suddenly became uneasy and cross; he often cried, and during the night shrieked without any apparent cause. At the end of a week a fit of suffocation came on, which lasted half a second; the child turned blue, and seemed dying, when after an acute shriek the respiration was restored. These fits came on frequently, and lasted from six to eight seconds. At the expiration of two weeks new symptoms appeared, the hands were convulsed, the thumbs bent into the palms of the hand, while the fingers were flexed the contrary way; convulsions came on once a week, then every day, then twice in the twenty-four hours. "Three months passed thus, the disease made rapid strides, and all the remedies employed produced no satisfactory results; calomel, emetics, and antispasmodics, had been tried and abandoned. At this period it was remarked, by chance, that the child scarcely moved its lower limbs, and this fact led to an examination of the spinal column, when upon reaching the third and fourth cervical vertebra, the patient uttered a piercing shriek. Four leeches were immediately applied; a few hours afterwards a fit of suffocation came on, but of short duration. Two days after the leeches were re-applied, and produced a miraculous effect. All the symptoms disappeared.

Cerebral affections are often found to produce epilepsy, and physiology shows the influence of the medulla on the respiratory apparatus; and inflammation of the spinal cord may be easily induced in children by external violence, owing to the want of thickness of the soft parts in early age.

Alteration of the lymphatic ganglia of the neck and chest, often produces crowing inspirations; the child feels suffocated, respiration is arrested, and only re-established when a piercing shriek is heard, evidently resulting from a contraction of the glottis. It most frequently occurs at night; is violent; the head and trunk are thrown backwards, and the face is pale and convulsed, the eyes fixed and turned, and the limbs contracted. Scrofulous children are usually the victims.

"Hypertrophy of the thymus" is the fourth cause which determines the spasm of the glottis; but our ignorance as to the uses, mode of development, and disappearance of the gland, has led to many doubtful points. "Is hypertrophy of the thymus congenital, or is it always acquired?" "Which are the physiological connexions inviting this alteration to lesions of the heart, by which it is so often accompanied, dilatation of the right cavities, and hypertrophy of the left ventricle?" These queries he is unable to answer. It is certainly evident that hypertrophy of the "thymus," like that of the lymphatic ganglia, produces "spasm of the glottis," by exercising pressure on the ninth pair of nerves. On a post-mortem examination it is found that the "thymus" is principally developed in the upper part, frequently extending to the jugular veins. It is easy, then, to understand, that the obstacle thrown in the way of the venous circulation of the head, will cause "meningitis;" and pressure upon the ninth pair of nerves, will cause "spasm of the glottis."

Case 3.—The following case came under his observation in November, 1853. A child nine months of age, born of healthy parents, lively and cheerful, took the breast with avidity, seldom cried; it was remarked by the parents how different he was from all the other children, for they had been as cross and ugly as this one was good-natured. The night before seen by him, after sleeping quietly for some four or five hours, the child awoke suddenly with all the symptoms of "spasm of the glottis." The attack only lasted a few seconds, when the little patient fell asleep. The next day the child appeared as well as usual. The ensuing night there was another attack; and from that time the fits came on regularly every night. Very soon they made their appearance during the day; were longer and more violent; crying, laughing, or eating, would give rise to them.

November 24th.—The child had a decided attack in the night, followed by convulsions, which continued for about twenty minutes, the carotids throbbing violently, the head and occiput unusually warm, pupils contracted, bowels constipated. Ordered leeches on the sub-sternal fossa, ice on the head, calomel, and iodide potass with belladonna.

November 25th.—Convulsions violent, the bowels had

moved freely, the skin very hot and dry, had had several attacks of suffocation.

November 26th.—The cheeks are red, the eyes prominent; the child, after vomiting, fell into a comatose state. Ordered leeches behind the ears, croton oil to the nape of the neck, sinapisms to the feet and legs.

November 27th.—Passed a bad night; the convulsions and fits of suffocation continued almost without interruption, the hands clenched, the pulse filiform.

The following day the child died, during an attack of suffocation.

Post-mortem examination, twenty-four hours after death, revealed the following: The thymus gland, which nearly covered all the anterior part of the chest, extending from the larynx to the diaphragm, and from one costal edge to the other. The lungs and pericardium were entirely concealed by the enormous mass which compressed the jugular veins at their origin; the mass weighed thirteen drachms and forty-two grains. The jugular veins were dilated, and, with all the veins of the neck, contained a large quantity of thick black blood. The lungs, though slightly developed, were healthy; the right cavities of the heart pale and soft; the left ventricle thicker than usual; the head well formed. The lateral ventricles contained about an ounce of bloody serum; the choroid plexus strongly injected; all the other organs normal.

Evidently, in this case, "hypertrophy of the thymus" was the primary affection, first producing the fits of suffocation, and later acute hydrocephalus, of which the convulsions were merely a symptom.

The differential diagnosis of "spasm of the glottis" is generally easily established:

1st. From *hooping-cough*, by the sudden appearance of the symptoms during the night, the complete suspension, and absence, of respiration and vomiting.

2d. From *croup*, by the nature of the shriek, and the normal return of the voice, and respiration.

3d. From *suffocation*, which sometimes succeeds prolonged cries, or passion; by the normal state of the pulse, the absence of cold limbs, fainting, and the pathognomonic (?) scream.

4th. From *cyanosis*, by being preceded by uneasiness, tears, groans, blue lips, less marked suffocation, and by the absence of *any shriek*.

A few words on the ætiology as bearing on the diagnosis, must suffice.

When "spasm of the glottis" is produced by inflammation of the brain or its membranes, or by chronic hydrocephalus, the cerebral symptoms necessarily first appear, and the fits of suffocation take place only when they have attained a certain degree of intensity; and the suffocation follows the same course as the encephalic affection, increasing or diminishing with it.

When "spasm of the glottis" is connected with inflammation of the medulla, there is generally some portion of the cervical region painful on pressure; suffocation is sometimes preceded by pain on the same part, and convulsions only take place in "*the thoracic limbs*," if produced "*by a fall.*"

"Spasm of the glottis," resulting from hypertrophy of the "ganglia," is met with in children of a scrofulous constitution, seldom before *the first year*, yet sometimes much later. It is frequently accompanied with cough and gastric derangement, and preceded by continual dyspnœa; and by forcing the child's head backwards, the hypertrophied cervical ganglia may almost always be felt.

Difficult as it is to recognise hypertrophy of the "thymus," the following symptoms will generally furnish a clue to a correct diagnosis: These are dyspnœa, most severe when lying on the back; a dulness over the region of the thymic gland; the tongue hanging out of the mouth, even during sleep. *Kopp*, *Graff*, and *Kommaul*, aver that these signs have never been observed except in cases where "spasm of the glottis was induced by hypertrophy of the thymus." When the disease is complicated by acute hydrocephalus, the fit of suffocation precedes the cerebral symptom.

The prognosis is always serious, as one single attack of suffocation may terminate fatally. The modifying influences are age, diathesis, probable cause, etc.

The treatment of "spasm of the glottis" presents two distinct indications. To arrest by the use of the most efficacious remedies the attack of suffocation: to combat the cause which may induce a return.

The resources in the first case are very few. The young patient must not be allowed to lie on his back; he must be carefully protected against cold and damp, and required to take moderate and regular exercise. Should he be strong and plethoric, moderation without weakening the vigorous constitution should be the rule; but if, on the contrary, he should be weak and anæmic, cod-liver oil, iron, etc., are indicated. Respiration being reëstablished, every precaution must be taken to avoid all causes that may give rise to another attack, thus: All sensations that may either induce immoderate joy or grief; violent running; the diet should be light, and of such a character as may be swallowed with little effort. Little of course is to be expected from any attempt to act directly on the thymus gland, although preparations of copper, small doses of calomel, ipecac, iodide potash, tartrate and citrate of iron, etc., together with the external use of iodine or croton oil, *seem* to favor its decrease. A blister on the chest will often prove beneficial.

After discussing the anatomy and physiology of the larynx, Dr. N. concluded that among predisposing causes may be reckoned:

1st, The peculiarity of distribution of the laryngeal nerves:

2d. The high degree of latent irritability that must exist around the sphincters of the air tube, owing to their nervous connexion:

3d. The contractors of the larynx, being more numerous, and more highly endowed with involuntary nervous energy than the dilators, indicated a desire to avoid complication in the mechanism of our being, by avoiding all unnecessary expenditure of muscular exertion in the performance of any given act. Now the larynx, in its quiescent state, is expanded, or rather dilated, such a state only being compatible with existence. Then the reason is very evident, why such a state should not require muscular exertion to maintain it so continually; for we know that the dilation of the glottis, even after the act of deglutition, depends more upon the elastic and erectile properties of the tissues adjoining this orifice, than upon mere muscular exertion. But the contraction of the larynx depends altogether on another source for its due performance. Here it is that the muscular exertion is brought into proper play, and here it is most required. If we swallow a portion of food, the larynx is hermetically sealed while the extraneous body is passing over it, and this is done by muscular exertion only; but the moment the alimentary bolus has passed into the œsophagus, the exciting cause being removed, the larynx immediately resumes its natural position, not by muscular exertion, but by its own elasticity, the antagonizing power of the constrictors of the larynx having given way. We know that this muscular arrangement is indispensably necessary, as without it life would cease. It is absolutely necessary that there should be some guarding

and controlling power over the orifices of this organ, that they may be closed against the slightest particle of offending matter presenting itself in their vicinity; and how beautifully has nature provided against such intrusions.

But if, in adult life, the larynx and its muscles are so highly endowed with sensibility, how much more so must they be in the infantile state, when the nervous system alone has the ascendency, ruling supreme over the entire system; morbidly alive to every impression, and governing the functions of the entire economy by its influence. We all know the wonderful changes which the larynx undergoes, from the period of infancy to that of puberty; the alteration in the calibre, and in the chordæ vocales. We are also aware that the young system, in progressing towards puberty, gradually loses that inordinate sensibility and irritability it possessed in infancy, and with it the larynx becomes less excitable, and more under the control of volition; hence it is that we seldom or never find laryngeal asthma attacking adults.

From the recorded history of this disease, from its near alliance to infantile convulsions, and from our own experience, we are led to the following conclusions:

1st. That laryngeal asthma, or the spasm of the glottis, is a disease peculiar to infancy, by which we mean any period within twelve months from birth.

2d. That those children who have not been nursed by the mother, are much more liable to the disease than others.

3d. That infants of nervous temperament are more subject to attacks of laryngeal asthma than those of a lymphatic or sanguineous constitution. In short, it appears to be purely a nervous disease; morbid anatomy has done little in clearing up the exact seat and nature of this disease, as there never has been found any evidence of inflammation in the supposed traits of the disease during those posthumous examinations we have on record.

Owing to the lateness of the hour, the Association then adjourned.

Correspondence.

THE TUNNEL UNDER LAKE MICHIGAN—THE CHICAGO BOARD OF HEALTH.

To the Editor of the Medical Record.

Sir—The twenty-fifth of March, 1867, was a day that will long be remembered with satisfaction by the inhabitants of Chicago; a day to be marked for ever with a white stone in the calendar of the city. The famous tunnel under the bed of the lake, excavated for the purpose of bringing pure water to the town, was formally opened by the civic authorities, and the Michigan water was admitted for the first time to the reservoir. For the first time, I say, because, though we have heretofore been nominally dependent upon the lake for our water-supply, it appears that, in consequence of the unfortunate location of the pumps at the water-works, we have been too much of the time furnished with either the sewage of the city from the mouth of the river, or with the filterings of the cemetery and the pest-house. For this the officers who located the water-works were not so much in fault as might be at first supposed. A quarter of a century ago an engine of ten-horse power, sucking water over the end of the wharf, was more than sufficient to supply the wants of the fur-traders; but when it became evident that Chicago was to be a city, the far-seeing authorities selected a spot far out of town, upon the lake shore, one mile north of the harbor. Here they erected an engine-house, with all the necessary machinery for supplying water. A stockade of piles driven into the clay, fenced in an acre of the lake, and thus the purity of the fluid was secured. Upon the provisions then made our citizens have been ever since dependent. But the growth of the town surpassed all expectation. A few years only elapsed before a line of breweries sprang up beyond the water-works. Population followed suit, and a thickly planted cemetery became conspicuous upon the high grounds near the lake. The river, too, was changed. Instead of the clear stream in which little boys had fished under the shade of the willow trees, it became a filthy cesspool, in which the contents of the sewers, the offal from the pork-packers, and the refuse of the distilleries, were thoroughly mingled by the keels of a thousand ships. All this matter was discharged into the lake, and was carried directly to the receiver at the water works, whenever a southerly wind turned the current in that direction. Great efforts were made to obviate the difficulty, but nothing seemed adequate to the occasion. At length the city engineer, Mr. Chesborough, proposed the excavation of a tunnel under the bed of the lake to a distance sufficient to insure communication with a body of water which could never be affected by causes operating along the shore. This plan was finally adopted, and the work was commenced about three years ago. A shaft was sunk near the lake to a depth of about eighty feet, and from the bottom of this well a tunnel five feet in diameter was carried horizontally at right angles with the coast. A huge *crib* was placed in the lake at a point two miles from the shore. Here another shaft was sunk to the required depth, and from that a countermine was carried inwards till it met the tunnel from the shore. The whole work was pushed through the bed of blue clay which underlies the lake, without quicksand or ledge of rock to interfere with the operations of the miners. Proceeding without accident or hindrance of any kind the enterprise was completed a few days ago, and was dedicated, amidst the rejoicings of the whole city, on the twenty-fifth day of March. We now receive the sweetest and purest water that can be found. Wholly free from sediment, it remains uninfluenced by the vicissitudes of wind and current which have been hitherto so strongly marked. The general use of such water cannot fail to remove from the community one of the most important of the predisposing causes of disease.

Another innovation fraught with blessings to our city has been recently inaugurated. We now have a board of health commissioners, similar to your Metropolitan Board of Health. This board consists of six commissioners, appointed by the judges of our Superior Court. Of these, three are physicians. The mayor is *ex officio* a member of the board, and is its president. The lay members are gentlemen of worth, who are desirous to accomplish all that lies in their power. Our profession is represented by Dr. John H. Rauch, formerly a professor in Rush Medical College, and well known, during the late war, for his remarkable executive abilities; by Prof. H. A. Johnson, of the Chicago Medical College, one of the most distinguished physicians in our city; and by Dr. William Wagner, a noted German surgeon. Thus constituted, the new commission has commenced work in earnest. The city has been divided into twenty-two districts, with a physician and a special policeman in each one to perform the duties of medical inspector and guardian of the public health. The duty of cleaning the streets is still retained by the Board of Public Works, but there is every possible manifestation of a

desire to act in accordance with the recommendations of the Board of Health. These new measures are well received by the citizens, and even the Irish are gratified by the official visits of the inspectors. The only obstacles to the efficiency of the board will arise from the magnitude of the area to be occupied by their supervision. While the Common Council, having control over the matter of salaries, misguided by an unfortunate piece of advice proffered by the Medical Society of the city, compel the commissioners to accept five hundred dollars a year as their only recompense, and while one of these overworked gentlemen has consented, without additional compensation, to discharge the duties of sanitary superintendent, shouldering this great burden in order, by saving the expense of such an officer, to render the new order of things more acceptable to the taxpayers, whatever credit may hereafter be assigned, none can ever be claimed by those who persistently opposed the adoption of all but their own pet measures for the public welfare. Secure of the approbation of an enlightened community, time will undoubtedly remedy many of the difficulties which are inseparable from every new enterprise. M.

Surgeon B. A. Clements has been transferred from the Department of the East to the Department of Dacotah. Surgeon C. H. Alden, and Assistant-Surgeon G. M. McGill, transferred from Department of the East to the Department of Missouri. Assistant-Surgeon Ely McClellan, transferred from Department of the East to District of New Mexico. Assistant-Surgeon W. R. Ramsey, transferred from Department of the East to the Department of the Platte. Assistant-Surgeons Samuel Adams and Henry McElderry, transferred from Department of the East to District of Texas.

Assistant-Surgeon C. R. Greenleaf, assigned with Examining Board at Louisville to relieve Surgeon Lewis Taylor.

THE FATE OF DR. LIVINGSTONE. — Information has reached the British Admiralty, which dispels the last faint hope of the fate of Dr. Livingstone. The *Times of India* publishes additional evidence that the great explorer is dead. An Arab had brought intelligence which leaves hardly any room for hope. If the man is to be believed, he saw poor Livingstone receive his death-blow.

THE LEAVENWORTH MEDICAL HERALD, is the title of a monthly to be issued June 1st, 1867, from Leavenworth, under the editorial supervision of Drs. C. A. Logan and T. Sinks. It is to consist of forty-eight pages of reading matter, and it is designed that its typographical make-up shall not be excelled by any similar journal in the older States. Its contents will consist of original communications from the active workers within its range of circulation; of the proceedings of the City, County, and State Societies; of reviews and book notices; of correlative scientific subjects; and of a monthly *melange* of the current medical literature of the day. The project commends itself to the physicians of Kansas, who we hope will not be backward with their literary and pecuniary contributions.

REMOVAL OF I. BAKER BROWN FROM OBSTETRICAL SOCIETY OF LONDON. — Dr. Baker Brown has been removed from the Obstetrical Society of London for alleged unprofessional conduct connected with the operation of clitoridectomy. The *Lancet*, after stating that the verdict bore no direct relation to the utility or usefulness of the particular operation, thus refers to the action of the Society: "The point which has lately been at issue was whether a Fellow of the Obstetrical Society was proved to have so far departed from the rules of professional honor as to render his retention in the Society an outrage upon the feelings of the Fellows, and a discredit to the profession of which they are members. The Society has expressed its conclusion, and this with a unanimity which precludes all doubt as to the necessity of the unusual step which has been taken. We may pronounce it as decided that the medical profession, speaking through a section of its body, utterly discountenances and repudiates the proceedings which have made one of their number notorious. It protests indignantly against the performance of a dreadful operation upon married women without the knowledge and consent of their husbands, and upon married or unmarried women without their own knowledge of the nature of the operation. It denounces the conduct of a surgeon who deliberately insults and compromises a fellow-practitioner by performing in his presence a mutilation as to which his sanction is unasked. It scorns the miserable quibbling by which a palpable want of veracity is sought to be defended."

Original Communications.

OSSEOUS TUMOR OF THE UPPER JAW.

By W. R. WHITEHEAD, M.D., etc.,

NEW YORK.

Osseous growths of the jaws present many points of interest, which are revealed by a careful study of their anatomical appearances and clinical features. It is a subject eminently worthy of remark, and might be appropriately considered at this time. I have, however, on a previous occasion endeavored to describe succinctly this variety of diseased growth of the upper jaw, in connection with other tumors of this region equally interesting and deserving of notice.* More than a general notice of the subject now would be departing from the simple design and original object of this communication; which is, the description of a case of excision of the superior maxilla, of peculiar importance, and attended with the most favorable results.

Case.—Miss F. P——, from the South, aged eighteen, of good constitution, well formed, and slightly above the medium size, was afflicted with a tumor of the upper jaw. She came to New York on the 28th of last December, and placed herself under my care for the purpose of having it removed. A few weeks prior to this date, I was consulted by her, at which time I examined the growth, and became acquainted with its previous history. At three years of age her nurse let her fall, and she received a blow, which bruised her right cheek; when six years old, a slight enlargement of the cheek on that side was first observed, which, however, was not very apparent, and caused her parents no uneasiness; but at the age of ten, the enlargement had sufficiently increased to excite their apprehensions.

Many medical gentlemen were consulted, who differed widely in their opinions regarding its nature. Topical remedies were ineffectually used, and constitutional means unavailingly essayed. About four years ago, the parents of the young lady visited Richmond with her, and consulted a distinguished surgeon, the late Dr. Chas. Bell Gibson, who advised the excision of the tumor. This gentleman expressed an unwillingness to give chloroform in the operation, and terrible apprehensions of pain deterred the parties from permitting it to be undertaken without the use of an anæsthetic. She suffered constantly from headache, during a year preceding the removal of the tumor. Two or three months previous to its excision, it grew rapidly, especially towards the orbit, and the headache increased with its extension in this direction. Last fall she had chills and fevers, which persisted irregularly until within a few weeks of the day of the operation. My first examination of the patient permitted me to observe that there was considerable deformity of the face, caused by a tumor occupying the right superior maxillary bone, slightly distorting the mouth, and making the cheek quite tense. This tumor invaded the orbit, and pressing upwards, narrowed the orbital cavity in its transverse direction, and compressed the eye. The roof of the mouth of the right side was slightly depressed. By passing the end of my index-finger behind the extremity of the alveolar arch, feeling and circumscribing the posterior and external surfaces of the tumor as thoroughly as possible, and carefully observing the deformity caused by it, I could judge with a certain degree of precision the extent of the disease. The mass appeared ovoid, had a smooth and regular surface, and to every part accessible to the touch was exceedingly hard on pressure, which was without pain.

The headache, from which she had so long suffered, appeared to be due to compression of the second branch of the trifacial nerve, and its anastomosing branches. The two last molar teeth were gone, and the remaining molar tooth was much decayed; the other teeth on that side were sound. The voice was but slightly nasal or indistinct. Mastication was not impaired to any extent, and the patient swallowed without difficulty. Apprehensions of the continued increase of the tumor, and its rapid extension recently towards the brain, excited the fears of the young lady, and caused her to desire the removal of this growth without unnecessary delay; and although its extirpation was the principal and most urgent reason for the operation, yet a very natural solicitude about the extent of deformity which might remain afterwards, was to her a source of considerable disquietude, and made me desirous to prevent, if possible, cicatricial marks about the face, resulting from incisions of the cheek, or other part conspicuously apparent.

Believing that moderate-sized tumors of the upper jaw could be removed without cutting the lip or cheek—an opinion which has already been expressed by Ferguson and some others, though not convincingly demonstrated—I experimented on the cadaver with a view to determine the degree of mobility of the parts about the mouth, and also the extent to which this cavity can be stretched by the use of well-adapted means. These experiments were simple, and appeared satisfactory. They consisted in exposing thoroughly the bony opening of the nares, by a dissection of the soft parts from the anterior nasal spine of the maxillæ, and thus facilitating the dissection of the anterior surface of either of these bones, as high up as the orbit, and rendering the nasal and malar processes quite accessible to bone-scissors and other instruments. By the use of cheek retractors, a gradual and very considerable dilatation of the mouth was effected. These experiments encouraged me to hope that I might be able to remove the tumor without cutting the lip or cheek of the patient. The only objection which occurred to me was, that the distension of the cheek or distortion of the parts might, if the mass were larger than previous examinations had enabled me to determine, render the anterior part of the tumor as high up as the orbit, inaccessible to dissection. Being prepared, however, as well as possible against all contingencies, and provided with suitable instruments, efficiently assisted, and ready to avail myself of any advantages which could not be anticipated, on the second of last January I proceeded to remove the diseased growth, and to test the value of the experiments previously made on the cadaver.

Operation.—The patient was seated in a dentist's chair procured for the occasion; and after she had taken a small quantity of brandy and water, ether was administered to her, and the operation commenced by detaching, with a pair of strong scissors, the soft parts from the anterior spine of the maxillæ, and partially exposing to view the anterior bony opening of the nares. At this time the patient commenced to vomit; she had, however, not taken any breakfast that morning, and the cause of the vomiting was attributed to the ether. Considerable delay was caused by this interruption of the operation. Ether was not again used, but after she had swallowed more brandy and water, she was rapidly made insensible to pain with chloroform, and my dissection of the gum from the tumor continued. The cheek retractors provided for forcibly stretching the orifice of the mouth were well applied, and produced a proper extent of dilatation, which could have been

* See Remarks on certain Tumors of the Superior Maxilla. New York Medical Journal. Vol. III. 1866. No. XVII.

much increased. I soon became convinced that the tumor in this case was too large and distended the cheek too much to be removed without an external incision. My previous opinion, predicated on the facility with which I could manipulate the parts on the cadaver, was modified by the peculiar extension upwards of this growth, which made its anterior and upper surfaces less accessible to instruments than could be anticipated before the preliminary incisions of the gum. Reserving, therefore, this operative procedure for a case more favorable to its adoption I promptly cut through the middle of the lip in its furrow, and extended the incision around and behind the right nostril, a short distance up the side of the nose. This incision, which is recommended by Ferguson, permitted me to complete the operation rapidly and with facility. The nasal branch of the maxilla was cut with Liston's bone-scissors, and the malar bone effectively severed with a metacarpal saw. An incision of the soft parts was then made along the posterior border of the palate bone, from the end of the alveolar arch to the middle palatine suture, and another at right angles to this incision, terminating at the alveolar of the left incisor, which was extracted. One blade of Liston's scissors was passed into the right opening of the bony nares, and the other into the mouth, and the palatine arch cut. The tumor was then wrenched out with a pair of Ferguson's lion forceps, and the remaining soft parts adherent to it were detached. One of the little palatine arteries, throwing out a fine jet of blood, was secured, after a little trouble, by a ligature; with this exception there was no trouble from hæmorrhage, but to guard against it considerable lint, some of which was saturated with a solution of Squibb's sub-sulphate of iron, was stuffed into the cavity left after the extirpation of the tumor.

The upper two-thirds of the external incision were united with ten or twelve silver wire sutures, and the cut surfaces of the lip were held in apposition with two figure-of-eight sutures. With the valuable assistance of Dr. Nathan Bozeman, now of this city, but late of Montgomery, Ala., this external incision was very neatly, accurately, and securely approximated throughout its entire length. After the application of a light dressing to the part, the patient was conveyed to her bed, and half a grain of sulphate of morphia prescribed, to be taken at night. In a few hours the pulse commenced to rise, and in the night she had considerable fever.

January 3.—Early in the morning I found the pulse 120; strong and full. She could swallow without difficulty; took strong beef-tea every few hours, and her mouth was often mopped out with a weak solution of chlorinated soda, and occasionally with glycerine. She took a few times during the day an anodyne and diaphoretic mixture, containing sulphate of morphia and swt. spts. of nitre; had very little thirst; she became restless, and late in the night her pulse increased to about 130.

January 4.—I saw her early in the morning, and commenced to give her stimulants; very soon after swallowing about half an ounce of sherry wine, her pulse was lowered eight or ten beats to the minute. She took frequently during the day brandy-whey, and beef essence; and eight drops of muriated tincture of iron in solution were administered to her every few hours. In the middle of the day her pulse was 120 to 124, and about the same at my evening visit. The same mouth-washes were used as at last visit.

January 5.—She continued to take the beef essence and tincture of iron as before; but substituted sherry wine for brandy-whey. By means of a rubber syringe with a long pipe, the upper part of her mouth was washed out several times with tepid suds of Castile soap; afterwards with clear water, and then with water containing a drop or two of creasote. In the evening she was quite restless, and had a hot dry skin, and her pulse was increased a few beats.

January 6.—I saw her at an early hour and found her much better; her pulse was only 96 to 100. Last night she was very uneasy and restless up to twelve o'clock; about that time she got rid of a lint plug which was annoying her; but soon afterwards she had a profuse perspiration, and improved rapidly. She told the attendants that she was glad that I would find her in the morning so much better. She complained of hunger, and drank her beef-tea very gratefully. To-day the hare-lip pins were removed, and the union of the lip was found to be perfect. The same detersive and medicated injections were used as yesterday. She took some chicken broth, and continued to take the beef essence and tincture of iron. A gentle aperient having failed to move her bowels, they were slightly relieved by a suitable clyster.

January 7.—Rested well last night; this morning a piece of lint became partially detached and caused her some discomfort; I removed this piece, and one or two others, with a pair of dressing forceps; syringed out the mouth with Castile suds, clear water, and weak creasote water. Continued the same medicines and nourishment. At the evening visit I removed two or three pieces of lint.

January 8.—Took out all the silver sutures; washed the parts and put fresh isinglass plaster to the lip and side of the nose, and removed all the lint plugs. I entertained doubts, as I had a few days before, whether the offensive suppuration caused by the lint, was fully compensated by the supposed security afforded against hæmorrhage by cramming the wound with this material. If all other necessary means for stopping hæmorrhage are made available, and the parts exposed sufficiently long to the air, I have no doubt that sometimes no lint would be required. It would be far better to have only the saliva, which is bland and unirritating, in contact with the surfaces of the wound, than lint. In a similar operation, about two years ago, which was attended with most excellent results, I abstained from stuffing lint into the cavity which remained after the excision of the tumor; and I believe that it would be well, if possible, always to adhere to this practice.

To-day, she is able to sit up and syringe out her mouth herself; has very little fever; said, at the morning visit, that she felt quite comfortable. Although I have requested her to observe strict silence, she will occasionally address a sprightly remark to her sister, or utter some pleasant expression, indicative of her habitually cheerful disposition.

January 9.—She continues to improve; has a relish for food; took some soft boiled eggs this morning; uses the same mouth washes; discontinued the tincture of iron.

January 10.—Last night she was restless, and about eleven o'clock she had considerable fever; I was told to-day that once or twice before she has had fever during the night. Fifteen grains of sulphate of quinia were prescribed to be given in clyster, but only a third of it at a time, and at three hours' interval.

January 11.—Doing very well; took in the same way as yesterday, twelve grains of quinine.

January 12.—She has not had a return of her fever; but the quinine was repeated once more.

January 18.—During the last six or eight days, she has been able to sit up and to walk about the house; and, if the weather were pleasant, could go out to walk. She went out this morning, in a closed carriage, and had her photograph taken, which, compared with

the one taken before the operation, exhibits a marked improvement in her personal appearance, effected by the operation that relieved her of this encroaching tumor. Desirous of having the deficiency of the upper-jaw, caused by excision of the tumor, repaired by some competent dentist, I made careful inquiry, and learned through a professional friend, that in a similar operation performed in 1842 by Dr. R. D. Mussy, of Cincinnati, on the patient Thomas McGilligan, Dr. H. Crane, dentist of this city, made a substitute for the upper maxillary bone which the patient had worn twelve years when last seen. The contrivance which the dentist Cook made, and to which Mussy refers in his publication of the case, was soon rejected by the patient as useless. Miss P. visited to-day the rooms of Dr. Crane, who is an ingenious and skilful dentist. With a little effort she can articulate quite distinctly; this is a very considerable advantage, and will aid in obtaining an excellent result, when this gentleman makes for her an artificial palate and set of teeth.

January 23.—She left to-day for her home. About two weeks after the operation, she was well enough to leave, but was detained by snow storms, which interrupted railway travel. I have recently received a letter from her, dated February 6th, and will quote a few lines from it:

"I am improving very rapidly, my color has returned with my strength, and I am sure I have already gained several pounds in weight; the soreness has almost entirely left my mouth, and it is healing up very nicely."

April 3.—Miss P. has returned to New York to place herself under the care of the dentist. The parts are entirely healed; she is no longer subject to headache, and is in the most excellent health and spirits. The space left after the extirpation of the tumor, has closed up remarkably well; the entire soft palate is preserved; and the only opening in the roof of the mouth is an oval orifice about an inch and a quarter in its longest diameter, which is antero-posterior. The eye is well retained in its natural position, and its movements are free, and easily executed. There is some flatness of the cheek, and distortion of the right side of the mouth, which is obviously caused by the disuse of the muscles on that side of the face, which defect can probably be removed by the device of the dentist.

April 18.—Dr. Crane has been eminently successful in accurately fitting to the young lady's mouth an ingenious piece of workmanship, composed in part of vulcanite, with a beautiful arch of teeth, and rose-colored gums of porcelain, appearing so natural that they defy close scrutiny. This dental attachment, which she has worn several days, enables her to pronounce with perfect distinctness; it improves her appearance, and her mouth feels more comfortable with it than without it, as it causes not the slightest irritation or inconvenience; indeed it is a most remarkable triumph of the dental art, and has, I believe, never been excelled. Having accomplished the object of her last visit to New York, she is ready to return to her home, and now enjoys social intercourse with a zest which she rarely experienced before the removal of the tumor.

Examination of the Tumor.—The tumor, after its excision, was heavy and hard, and appeared like a compact mass of hypertrophied bone, weighed four ounces and a quarter, and involves the superior maxilla and part of the malar bone. The greatest thickness of this growth is measured by its vertical diameter; its superior surface corresponds to the floor of the orbit, which before the operation, in being displaced upwards, diminished the orbital cavity in this direction to the extent of about half an inch. The inner fractured border of this surface corresponds to the lower border of the orbital plate of the ethmoid bone, from which the tumor was separated in wrenching it out. On the upper third of its anterior surface may be seen an indentation, corresponding to the external orifice of the suborbital canal, from which point may be measured with the eye the extent of encroachment of the tumor upwards. Its external surface projects quite prominently, and its inferior and posterior surfaces also exhibit considerable enlargement of the maxillary bone. A piece of the tumor was sliced out by sawing to its centre; and the internal structure of the mass was observed to be similar to that of the most compact bone tumor, and which is known as the ivory exostosis. Exceedingly fine sections of this piece were placed on slips of glass, and successively examined, under the microscope, after adding a drop of glycerine to each delicate section, and pressing gently its thin glass cover. Numerous osseous lacunæ with their diverging canaliculi, were seen thickly studding the little masses within the field of the instrument. These osseous lacunæ were found to be present in each specimen examined, though not so numerous in some as in others.

The tumor seems to be formed exclusively of bone tissue, and may be considered as a type of dense osseous tumors of the superior maxilla, and belongs to an interesting variety of benign growths.

Conclusions.—The growth is of a benign character. The origin of the diseased action in the bone is traceable to a contusion.

The upward extension of the tumor was peculiarly unfavorable: the mass invaded slowly the orbital cavity, and probably would ultimately have caused a protrusion of the eye and an encroachment on the brain.

My experience in this and a previous case of excision of the superior maxilla has been entirely favorable to the use of chloroform in this operation. As an excellent precautionary measure, it is well to give brandy in this, as in other surgical operations, before administering chloroform: the brandy facilitates the action of the chloroform, and materially diminishes the chances of accident resulting from the depressing effects of this agent on the nervous system.

I believe that tumors of the upper jaw of a moderate size, when favorably situated, may be excised without an external incision of the face.

The incision in the furrow of the lip and up the side of the nose, offers peculiar advantages over other incisions of the face.

The structure of the tumor will influence the amount of hæmorrhage; causing it to be more or less dangerous and difficult to control, in proportion to the vascularity of the growth.

It is best, if possible, not to stuff lint into the cavity left after the extirpation of the tumor; leaving the parts to the bland and unirritating contact of the saliva.

An excellent substitute of vulcanite and porcelain may be made to repair the deficiency caused by excision of the upper maxillary bone; and thus the skill of the dentist may essentially aid in correcting the contraction of the parts after healing.

A removal of the entire floor of the orbit does not necessarily cause a falling of the eye; such was not the case after this operation.

New Hospital in Cincinnati.—A new hospital, to be known as the Commercial, is to be erected in Cincinnati, at a cost of 500,000 dollars.

A REMARKABLE CASE

OF PENETRATING AND LACERATED WOUND OF THE ABDOMEN AND UTERUS OF A PREGNANT WOMAN,

WITH ESCAPE OF A LIVING CHILD THROUGH THE WOUND.

By E. J. MARSH, M.D.,

ASSISTANT SURGEON, UNITED STATES ARMY.

On the evening of April 5, 1867, Mrs. F., aged 42, the mother of eight children, and then in the eighth month of pregnancy, was struck in the abdomen by the horn of an enraged cow. The horn did not tear through her clothes, but she felt the child drop out, caught it in her dress, and took a few steps homeward. Here she was met by a neighbor, who assisted her to the house, distant about twelve yards from the place of accident. With this assistance Mrs. F. walked to the house, and then sat down, but the neighbors soon laid her on the floor. Her friends up to this time, supposed that the child had come *per vias naturales*, but when they lifted up the clothes they found the bowels protruding, and "reaching to the feet," as one of them stated. They cut the umbilical cord, removed the child, endeavored to replace the bowels as far as possible, covered them with a clean cloth, and left her in this condition until my arrival.

I arrived at the house about three-quarters of an hour after the accident, and found the woman lying on the floor, extremely prostrated, pale, and with a rapid and barely perceptible pulse. There was a considerable, but not excessive amount of blood, soaked into her clothes, and on the next morning blood was found on the ground where the accident occurred, and thence to the house.

I removed her to a mattress, and, on examination, found several feet of intestine and the uterus lying exposed, protruding through a wound of the abdominal wall. The womb was partially inverted through a wound in itself, and the placenta was still attached to the surface of the inverted portion. The wall of the abdomen was torn for about five inches, the wound extending from the umbilicus outwards and somewhat downwards on the left side, in an almost straight line. I returned the intestines, removed the placenta, and replaced the uterus. This organ was considerably lacerated, the wound being Y-shaped, but with one leg shorter than the other. In the contracted state, the wound was between two and three inches in length. There was but slight uterine hæmorrhage on the removal of the placenta. I then united the wound with sutures, plaster, and put on a broad bandage. She was entirely conscious, complained little of pain, but was very restless, throwing her arms about and rolling about the bed. I had given her constantly from my arrival small quantities of brandy and water, but she did not in the least rally from the shock; the pulse soon became imperceptible, and in about an hour and a half from the reception of the injury, she died.

The child was a boy, was not injured in any way, and is still living.

West Point, N. Y., April 18, 1867.

A Blessing in Disguise.—A distinguished London surgeon has taken the lecture-room to reassure the ladies in regard to the "chignon fallacy." He says the "organisms" are neither entozoa nor epizoa, but only ectozoa, which are comparatively harmless, and, indeed, aid the circulation of the blood by compelling the pleasant exercise of scratching.—*Exchange.*

THE MEDICAL USE OF ELECTRICITY.

By G. M. BEARD, M.D., and A. D. ROCKWELL, M.D.,

OF NEW YORK.

No. IV.

SYNOVITIS.

Mr. Geo. L., aged 35, stated that about the 1st of July, 1866, he was sunstruck; and between the 20th of the same month and the 15th of August, he suffered from three strokes of paralysis, resulting finally in total blindness. His sight gradually returned, but by degrees his shoulders became lame and stiff, so that he could with difficulty use them. This state of things continued until about the middle of September, when both knees and ankles commenced to enlarge. In November, when the patient applied to us for treatment, we found him suffering from severe sub-acute synovitis. Both knees were enormously swollen, the fluid having accumulated to such an extent that the patellæ projected forward more than an inch. Four applications were given, one every day, but with no marked effect, except that the lameness of the shoulders and ankles was much relieved.

He then left the city and was absent one week. On his return the improvement was found to be very great. The accumulation of fluid in the knees had almost entirely disappeared, and the swelling reduced in proportion. At first, the very strongest current from Kidder's apparatus made no impression, when applied down the spine. The legs were but little sensitive to the electric stream, and the feet and toes, which are generally very readily affected, were remarkably torpid. The applications were continued on Dec. 3d, 4th, 5th, 7th, and 9th, effectually removing this want of sensation, and completely dissipating the remaining swelling and tenderness of the knees.

PARALYSIS.

Case First.—Mrs. S. was first seen February 6, in consultation with Dr. Moreau Morris. Her history was, that about three years before she had given birth to a child, since which time she had been an invalid. She could walk only with difficulty, and by the aid of some support. A few weeks before we saw her, she had suffered an attack of what appeared to have been a rush of blood to the nervous centres, followed by increased weakness. She was of slender form, and was somewhat emaciated. She complained of persistent coldness in the feet, that at times was almost painful. Her appetite was capricious, her bowels very much constipated, and she was also annoyed with neuralgic pains in the left side. On examination, we found the muscles of both legs were inactive and shrunken, and were very slow to respond to electrical excitation. The flexors of the left leg had entirely lost their muscular contractility, and the whole limb presented an unhealthy aspect. The case appeared to be one of functional paralysis, associated with general debility. Whether this anæmic state was the result of some lesion of the nerve centre, it was manifestly difficult to determine. The indications for treatment in this case were,

1st. To improve the general condition by some effective tonic.

2d. To restore the muscular contractility and increase the blood circulation in the lower limbs.

As internal medication had been tried in vain, it was resolved to see what could be done by electricity alone, using general and local applications. During the first week of treatment the patient complained of some restlessness at night, but of no other unpleasant symptom.

From that time there has been a gradual progress. Her appetite has increased, her bowels have become more regular, and her rest at night is less disturbed. The pains in the side left her the third week of the treatment, and have returned but slightly on one or two occasions. Her muscular system throughout is somewhat firmer and harder, and consequently has very perceptibly improved in her general appearance. The circulation in her lower limbs has so far improved that she complains less of cold feet, and the color both of the right and left leg is more natural. She can walk about with greater ease and for a longer time than before, but more on account of the fact that her general vigor is greater, than from any special increase in the contractility of the affected limbs. We shall hereafter resort to the use of the continuous stream on the muscles of the lower extremities, still continuing our general tonic applications with the faradaic current. Anything like an absolute restoration in such cases is of course not to be expected.

Dr. Todd, of London, has advanced the idea first suggested by Marshall Hall, that by means of electric currents we can diagnosticate some of the different types of paralysis. His theory is that when the electro-muscular excitability of the affected part is lost, or nearly so, or is normal, we have a case of curable paralysis, caused either by lead poison, rheumatism, hysteria or exposure to cold, or by some other peripheral irritation; and when the electro-muscular excitability of the affected part is increased above the healthy standard, we have a case of incurable paralysis, connected with some persistent irritating brain lesion. These theories will, we believe, stand the test of experience.

Case Second.—W. G. was sent to us by Dr. Chalmers to be treated for anæsthesia, and partial loss of the power of motion of the thumb and fingers of the left hand. He stated that ten months previous he had suffered from swelling and pain in the left hand; that the "skin burst," and that he afterwards lost all sensation in the thumb and fingers. He was unable to grasp anything firmly.

He complained of a feeling of coldness in the affected parts, that, at times, was quite annoying. The skin was dry and shrivelled. His general health was so good that we employed only local applications, and those were as strong as he could possibly bear. Both the descending and ascending secondary currents were used, and the electrodes were applied along the course of the median nerve and its branches. The progress was slow but steady. The sensation gradually returned, and after fifteen applications was completely restored in all the parts except the tip of the second finger. He then returned to his occupation, which was that of a house-carpenter, and found that he could labor nearly as efficiently as ever. The feeling of coldness still continues to annoy him occasionally, more particularly in stormy weather.

Case Third.—Mr. C., a gentleman 60 years of age, represented that in October, 1864, he began to be affected with severe pains in his legs and feet, which were most severe at night, with alternations of heat and cold. The power of flexion and extension of the muscles of the leg gradually left him, until he could walk only with difficulty. The pain also left him, and a feeling of numbness, like that of a "foot asleep," remained, that was soon followed by entire loss of sensation. When he first came to us, Jan. 15, 1867, he could hardly raise his feet, saying that they felt "like dead weights." The loss of sensation and motion was more marked in the left foot than in the right. He was a large, well formed man, and, notwithstanding his age, appeared to be in quite vigorous health. On making the first application it was found that the muscular contractility was somewhat diminished, especially on the left leg; and the sensation was so blunted that he did not feel the entire force of the battery, even when the electrode was placed on the extremity of the toes. After four vigorous applications of the ascending and descending faradaic current (the positive pole being pressed against the ball of one foot, while the negative was applied to the other), the sensation in a good measure returned, and he found that he could flex and extend his toes with less difficulty. The same treatment, continued for a month, gave very favorable results. His gait was much more natural, and the sensation to a considerable extent returned in both feet.

Case Fourth.—Mr. S., a young man of about 30, was sent to us by Dr. Austin Flint, to be treated for paralysis of sensation of both legs, from which he had been suffering for nearly a year, caused by syphilis, as there was some reason for believing. Four or five applications were made without any observable results. The patient then left us scarcely any improved. Reasoning from analogy, it would seem that he might have been somewhat benefited by a long course of treatment.

INFANTILE PARALYSIS.

Case Fifth.—Nathan H., aged 3 years. During the month of July, 1866, the little patient was first brought for treatment. Both limbs were atrophied, the left more considerably than the right. The child was scarcely able to support his own weight. About a dozen applications were given, and with marked improvement, so far as warmth and strength of limbs were concerned. During the month of August the treatment was discontinued; but on the first of September, when the boy was again brought to continue the applications, he was able to walk alone and with comparative ease.

Case Sixth.—Benj. A., aged 3 years. His mother stated that eighteen months before (April, 1865), after suffering severely in teething, the paralysis first showed itself. For several months the child had been taken to public clinics, where cod-liver oil had been given, but with no decided improvement.

He was first brought for treatment about the 5th of September, 1866, and up to October 22, received fifteen applications of the faradaic current. When first seen, the legs were much atrophied. The circulation was deficient, and the limbs were powerless to bear the weight of the body. The improvement manifested, although very gradual, was encouraging; and it is to be regretted that the parents, who lived a considerable distance from the city, ceased to visit us. At the end of treatment, the little patient could easily stand, by the aid of a chair. The limbs had increased somewhat in size, and the warmth of both was much greater than six weeks before.

CHRONIC INFLAMMATIONS OF MUCOUS MEMBRANES.

Having always been taught that electricity was not good for inflammations, we were only convinced of the error of the theory by repeated observations of its beneficial effects on persons affected with catarrh and bronchitis, and ulceration of the membrana tympani.

We find that electricity is a powerful adjuvant in the treatment of all chronic inflammations of the pharynx, larynx, and nasal passages, both for its general tonic influence, and for its local corrective power. It allays the irritation caused by the application of nitrate of silver, and those upon whom we have employed it for this purpose, desire to have it repeated. Electricity has been long used in diseases of the ear with various

success. It is now known to all aurists that deafness, in the majority of cases, is a symptom of some form of inflammation of the auditory apparatus. It is therefore logical to infer that electricity would be of value in the treatment of such maladies, and so we have found it in a number of cases.

Case First.—Elisha L., aged 17. When five years of age he was attacked with scarlatina. A few weeks after recovery he was pulled violently by both ears, since which time he had been very deaf, and could with difficulty be made to hear when spoken to in a boisterous tone of voice. We first saw him Jan. 24, 1867, when he could hear the tick of a watch only when it was pressed firmly against the ear. The membranæ tympani were somewhat thickened, and there were evidences of inflammation in the right external auditory canal. For the sake of experiment, we concluded to test the effects of electricity, directing the patient to place his hands on the piece of copper to which the negative pole was attached, and applying the positive below and anterior to the auricle. At the close of the operation he could hear the watch four inches on each side. On the next visit we found that he retained all that he had gained, and could hear conversation much easier than at first. We then inflated the tympanic cavities by Politzer's apparatus, with the result of increasing the hearing-distance two inches on each side. We had intentionally delayed this very important operation in order to see first what might be accomplished by electricity alone. The tubes were readily permeable. The patient shortly after left the city, and we have had no information in regard to his subsequent progress.

In cases of ulceration of the membrana tympani and chronic inflammation of the middle ear, accompanied by offensive discharge, and associated with deficient vital force, we have found that general tonic applications wonderfully assist the local treatment of syringing and astringents. Of those patients whom we treat for pharyngitis and ulceration of the membrana tympani, those upon whom we employ electricity as an adjuvant seem to progress more rapidly and more satisfactorily than those upon whom we do not; and so marked is the difference in the results that we now rarely treat such cases for any length of time without resorting either to general or local applications.

Case Second.—George B., of Conn., a lad of 14, when ten years old had suffered from the measles, that had left him with ulceration of the membrana tympani, and inflammation of the middle ear on the left side, attended with abundant and offensive discharge. A few months before he called upon us the right ear had also commenced to discharge, and some alarming symptoms of vertigo began to manifest themselves. The pharynx was affected with follicular inflammation, as usually obtains in such cases, and an annoying, persistent cough made his friends apprehensive of tuberculosis. His appetite was capricious, his muscles flabby, and his general condition below par.

Examination by the mirror and speculum revealed the absence of the left drum, and a small perforation on the inferior portion of the right. The hearing distance of the left ear was three inches; of the right, two feet. The eustachian tubes were pervious.

Dr. D. B. St. John Roosa afterwards saw the case in consultation, and confirmed the somewhat unfavorable prognosis that we felt compelled to give. It should be stated, moreover, that the lad had been treated for his difficulty by various physicians. At one time he submitted to constant blistering over the mastoid process, for several months. We decided to employ both general and local treatment. The ears were ordered to be syringed with lukewarm water every night, after which a solution of sulphate of zinc (grs. iv. to ʒ j.) was to be dropped in and retained for a few minutes, while the patient inflated the tympanic cavities by closing the mouth and nostrils and blowing vigorously. He visited us over a week regularly, at which times we usually treated his pharynx by applications of a solution of nitrate of silver, of moderate strength, or by a solution of permanganate of potash, and inflated and cleansed the tympanic cavities by Politzer's apparatus. There was immediate temporary improvement of the hearing; but for the first month there was no perceptible diminution of the discharge. We then began to make use of general applications of the descending faradaic current over the whole body, and particularly below and anterior to each auricle, pressing the fingers firmly against the skin. It was not long before good effects were manifest, so far as his general health was concerned, although the condition of his ears improved but slightly. Whereas, at first, he was much fatigued by the mere exertion of coming to the city and visiting the office, he could now join with alacrity in the vigorous sports of his companions. By the 1st of February, 1867, the attacks of vertigo became very unfrequent, the appetite had increased in sharpness, the sleep was sound and undisturbed, the pharyngeal inflammation and the vexatious cough had entirely disappeared, and he had gained several pounds in flesh. We now added the internal administration of iron to the other remedies; but continued on with the use of the ear-drops, and the general applications of electricity. By the 1st of March the discharge from the right ear had entirely ceased, and in the left had greatly subsided. Calcined magnesia, blown in a few times against the inflamed surface, at this time seemed to operate favorably, and the patient was directed to come occasionally for general applications, mostly discontinuing the local treatment. The hearing distance had increased on the right side one foot, and on the left two feet. In this case the agents employed to combat the local inflammation and general debility were so numerous and so varied, that it is impossible to determine with accuracy just how far the amelioration was due to the application of electricity. But as little or no progress was made while mere local treatment was employed, and inasmuch as after we began the tonic applications all unpleasant accompanying symptoms—the barking cough, the irritation in the throat, vertigo, and general weakness—disappeared, we naturally infer that the electricity was a very important if not indispensable adjuvant to the other remedies.

Case Third.—Mr. L., a clergyman from Brooklyn, came to us Dec. 15, 1866, complaining of a throat difficulty of fifteen years' standing that at times had made it very difficult for him to fulfil his duties in the pulpit. Occasionally he had been compelled to rest entirely, for a considerable interval, from all public speaking. He complained of a feeling of heat and dryness in the throat, and of continued hoarseness, that increased at times so that he could only speak in a whisper, and also of a very annoying and persistent cough. His pharynx was so exceedingly irritable that we found it very difficult at first to make a satisfactory laryngoscopic examination; but this sensitiveness was in a measure overcome by perseverance, and we were enabled to gain the vocal cords, and inspect the upper portion of the trachea. We found the entire mucous membrane of the pharynx and larynx affected with follicular inflammation. The secretion was abundant, especially in the vicinity of the vocal cords. Physical

examination of the lungs convinced us that his cough was mainly the result of chronic bronchitis, and, as his general health was excellent, we decided to employ local applications of nitrate of silver, and to make use of inhalations, giving no constitutional treatment whatever. He visited us two or three times a week, and soon began to improve slightly; but as we were not satisfied with the progress he made, we employed local applications of electricity. The results were unexpected. Not only were the irritating effects of the applications of nitrate of silver temporarily relieved, but permanently beneficial results seemed to follow at once, both for the throat affection, and more especially for the cough, which all along had been one of his most distressing symptoms. When he discontinued the treatment the cough had almost entirely disappeared, and the inflammation of the larynx was in a good degree subdued. His vocal cords also were stronger; but we advised him to rest for a while from his public labors, in order to avoid the danger of any relapse.

Original Lectures.

OPERATION FOR HARE-LIP,

WITH REMARKS

By PROF. FRANK H. HAMILTON, M.D.,

BEFORE THE CLASS OF '65—'66 OF

BELLEVUE HOSPITAL MEDICAL COLLEGE.

Gentlemen:—We bring before you to-day a child, six days old, having single hare-lip, complicated with fissure of the palate. Hare-lip, or Labium Leporinum, as it is technically termed, is so called from its resemblance to the upper lip of the hare. There are two principal forms of hare-lip, namely, simple and complicated. By simple hare-lip we mean that in which there is a fissure in the lip only; by a complicated hare-lip we mean that in which there is a fissure in the lip, and also a fissure, more or less extensive, in the roof of the mouth, or in the alveolar arcade. The simple hare-lip may be either single or double; that is, it may exist on one side, or upon both. The complicated forms of hare-lip also admit of division into several varieties, but which we will not stop now to describe particularly.

Hare-lip is a congenital affection, and is the result of an arrest of development. The upper lip being formed from three points, viz. a central, and two lateral points, the arrest of development necessarily results in the formation of a fissure upon one side, or upon both.

My mode of procedure in operating for hare-lip differs somewhat from that usually practised; and in order that you may understand the value of my experience upon this subject I have thought it proper to bring before you a tabulated statement of most of the cases upon which I have made operations in the course of my life; which have been compiled by a very intelligent young friend of mine, Dr. Thayer. He has taken them from my various note-books, and from the published accounts of my clinics, and has arranged them in a convenient form for reference. The number which he has thus tabulated is forty-four (excluding two, which he has very rightly rejected as not being properly cases of hare-lip). I have been able to find in addition five cases, so that this operation will constitute the fiftieth which I have made for hare-lip. But the analysis which I offer you of my cases is based upon these forty-nine, which are here tabulated.

In the first place I have to say that but three times in all of the cases upon which I have made the operation, have I failed to make the lip unite; one of these was the first case in which I ever made the operation for hare-lip, and in which I committed the double mistake of employing hare-lip pins, and committing the patient subsequently to the charge of another person for treatment. It is an established maxim with me now never to undertake an operation for hare-lip, unless I can have the case under my own treatment subsequently; believing that in a branch of surgery, in which so much depends upon minute detail both in regard to the operation and the subsequent dressings, the operator neither does justice to himself nor to his patient, who submits the case subsequently to the care of less experienced persons. Indeed, I would apply this rule, with few exceptions, to the practice of any department of surgery, which is insomuch an art that it can only be acquired and practised skilfully by those who have often repeated the same manipulation. When I made my first operation for hare-lip I had heard the remarks of Roux, the great French surgeon, who had declared that two successful results out of every three operations were all that could be ordinarily expected. My experience does not confirm the accuracy of this statement. I shall presently describe to you, with considerable minuteness, my own method, which, it will be observed, is exceedingly simple, both as regards the mode of procedure and the instruments employed.

The first question which would naturally arise in this connexion would be at what period of life is it proper or best to make the operation? I reply in general terms, other things being equal, the earlier it is made the better; for the reason, first, that the earlier the operation is made the less the child will have to dread; second, the earlier the operation is made, in my opinion, the less the patient will actually suffer from the operation; third, the more prompt will be the union; fourth, the more perfect will be the configuration of the lip in subsequent life; fifth, if it is a complicated hare-lip, with fissure of the alveoli, or of the roof of the mouth, the earlier the operation is made, the more closely the sides of this long fissure will eventually approximate: and finally, the earlier it is made the more sure we are of avoiding those future contingencies which from time to time may arise, and which may render a final and complete deferring of the operation necessary. For example, if the child is in complete health at the period of birth, we cannot be sure that it will be in equal health again at any subsequent period. If the child is free from eruptive affections, we cannot be sure that such eruptive affections may not at any moment develop; which eruptions I regard as in themselves constituting a sufficient ground for deferring the operation. Third, we shall have to omit to make the operation during the heat of the summer; it having been my experience that operations of this kind, made upon infants or young children in summer, are exceedingly liable to prove fatal, owing to the fact that at this season of the year all infants are prone to affections of the alimentary canal; and if we add to the proneness to diarrhœal affections induced by season, the provocation of an operation, the danger from this cause becomes not inconsiderable. Fourth, it is not, in my judgment, proper to operate during the period of teething; and if we delay the operation until after teething has commenced and terminated, then various circumstances may, and are very likely to interpose to prevent the completion of the operation at any subsequent period; moreover, by the delay we have deprived ourselves of the advantages which have already been mentioned as belonging to the operation made in early infancy. I have not had an opportunity of making an operation on the

first day after the birth of the child; yet I would not hesitate to do so, if the case were presented, and the condition of the child, with the season of the year, were favorable. The earliest operation which I have made, up to this moment, has been on the tenth day: and from this period I have operated on all ages up to thirty-five years of life. Ten days, it was said some years ago, was the youngest age at which the operation for hare-lip had been performed at King's College Hospital in London. Dr. Friedberg has operated three hours after birth, ten hours after birth, and fourteen hours after birth; Bateman has operated four hours after birth; Dawson has operated seven hours after birth; Malgaigne at nine hours; Dubois and Guersant also performed early operations.

I will now proceed to describe, with more particularity, my own method of operating. I employ in this operation no instruments but a common bistoury, a very heavy and strong-bladed, sharp pair of scissors, so constructed as that they will not yield, and thus compress without cutting the tissues, and a common straight surgeon's needle, or one slightly curved at the point. I employ also harness-maker's silk, or the ordinary surgeon's silk, of large size, as a suture. Hare-lip pins, introduced by Ambrose Parè, and generally employed by surgeons, from his time down to the present period, I have never used since my first operation, which I have described as a failure. I find no good argument for their use; on the contrary, I find plenty of substantial arguments against their use, and I have come to regard them as a relic of barbarism. In addition to the sutures I employ also common adhesive plaster, in a manner which I will hereafter describe.

In regard to the use of anæsthetics in this operation, I may say that I have occasionally employed them, and I have not seen from them any ill effects. Infants pass under the influence of the anæsthetic promptly, and its immediate and final effect upon the circulation is less marked than is the case with adults. Nor do I know of an authenticated example in which the life of an infant has been destroyed, either directly or indirectly, by the use of ether or chloroform. But inasmuch as the patients do not suffer from apprehension in prospect of the operation, and the operation can be quickly made, and is not apparently an exceedingly painful one, rather for the purpose of saving time than otherwise, I have usually, even since the introduction of anæsthetics, omitted to give them. I will, however, in this case put the patient moderately under the influence of ether before proceeding to the operation.

(This was done, the patient not being completely insensible, and Dr. Hamilton then proceeded to make the operation, adding the following description.)

I seize the lip upon the side—if it is a single fissure, as in this instance—on which the fissure exists; dissect up the attachment of the lip to the gums, and pursue the dissection until I have completely elevated the ala of the nose upon that side, which is always greatly displaced; and without this precaution it will be more difficult to bring the lips together, and the ala of the nose will remain permanently displaced. I then proceed to the opposite side and dissect rapidly the slight attachments of the margin of the lip to the gums in this direction also. I now seize one margin of the lip between the thumb and finger of my left hand, and with my strong and sharp scissors, I cut away a straight ribbon, carrying the scissors well up into the ala of the nose, if the fissure extends so far. I then seize the opposite side in the same manner, and remove a ribbon from the margin of the fissure in the same manner. My purpose always is, to *remove enough*, so as to make the surfaces which are to be brought into apposition as broad as possible. I remember once to have witnessed an operation for vesico-vaginal fistula, made by that distinguished surgeon, Dr. Simms. And when he had completed his operation, I said to him, "Doctor, I have discovered the great secret of your success in operating for vesico-vaginal fistula. It is, I think, first, in making a very broad and free incision of the margins of the fissure; second, in introducing your sutures far from the edge." The Doctor acknowledged that this constituted the great part of the source of his success.

I never use a bistoury for the purpose of cutting the edge of the fissure; for the reason that, however sharp it may be, it is almost impossible to make the line of incision straight; and it is difficult to secure the requisite breadth of surface. Nor do I deem it necessary to use any of those curiously constructed forceps which are employed by some surgeons, for the purpose of seizing the lip and indicating the direction in which the incision shall be made.

If, at this moment, the coronary artery springs with a vigorous jet, I direct the assistants to seize upon the upper lip on either side of the fissure, and hold it firmly until I am able to introduce my sutures. I introduce my first suture at the point of junction of the vermilion border of the lip with the skin, and pass it directly through to the interior surface of the mouth; the same point of junction of the vermilion border with the skin upon the opposite side, indicates the point at which the needle must emerge in this direction. I introduce this lower suture first, in order that I may bring the lower margins of the lip together for a moment, and be able to determine precisely at what point upon the opposing surfaces of the fissure the next suture should be passed. The second suture—and it is seldom that I use more than two, unless it is in adults—I introduce, close to the ala of the nose on the side of the face on which the fissure exists; and bring it out on the opposite side at such a point as has been determined by the immediately preceding measurement, is proper. Both of these sutures are introduced far from the edge. In a child of this age I introduce them at least a quarter of an inch from the edge. If the fissure was very wide, I would introduce them half an inch from the edge. And in children who are older, in whom the skin is less extensile, it is my general practice to introduce the suture half an inch from the freshened margins of the fissure. I now close the upper suture first, this part of the fissure requiring the least strain, and bring the opposing surfaces in apposition, and tie with an ordinary surgeon's knot, snugly. I then close the lower suture in a similar manner. Whatever hæmorrhage has occurred from the coronary vessels, now immediately ceases, the tightness of the sutures being always adequate to arrest the hæmorrhage in these vessels. I do not now apply, as some have recommended, a small delicate suture to the free vermilion border of the lip, for the purpose of avoiding the slight indentation at this point, which occasionally occurs after the completion of the operation, finding that the suture passing through the free vermilion border holds upon tissues which are so exceedingly frail and delicate that it scarcely ever fails to work its way out in the course of a few hours, or a few days at most, after the operation is made. I have used this suture a few times, but it serves no useful purpose. Now the operation is completed by placing across the upper lip from one side of the face to the opposite, strong bands of adhesive plaster, drawing the lips together with as much firmness as possible; so, indeed, as to corrugate the mouth into a very unseemly shape. The object of these adhesive plasters is to take off at once all strain, as far as possible, which has been resting upon the sutures; and to leave to the adhesive plasters

rather than to the sutures, the task of supporting the lips; the sutures serving the purpose, mainly, of keeping a more accurate adjustment of the margins of the fissure, and standing as a "reserve" in case the adhesive plaster should give way. These adhesive plasters should be broad upon the surface of the cheek, and comparatively narrow as they cross the upper lip. It is not necessary to retain them in place by bandages, or compresses, ordinarily. When these plasters are thus applied, I add two or three narrow strips of adhesive plaster upon the lower portion of the upper lip, for another purpose. I have observed that if the lower margin of the lip is not covered by the adhesive plaster, it becomes dry, soon swells, rolls out, and cracks open, and the process of union is defeated at this point. While, if it is covered in by the adhesive plaster—the plaster imbricating the lower margin of the lip to the extent of from a quarter to half an inch, it serves to compress the lower part of the lip and to prevent its swelling out; it keeps it in a state of moisture, which is more favorable to the reduction of inflammatory action; and what is of equal importance, it protects the lip from the spoon employed by the nurse in feeding the child.

In the further treatment of this case, it is my practice to see the patient, if possible, twice daily, morning and night. If I find that the plasters have slipped a little upon the face, or have become moistened, through the carelessness of the nurse in feeding the patient, and thus have been permitted to stretch, I direct the assistant to stand behind the head of the patient, and to press the cheeks forward well, while I cut the centre of one or more of the straps, remove them from one side and the other, and substitute for them fresh straps, paying no regard to the fact that the straps which remain may be thus more or less doubled up into folds across the top of the lip, for these are certain to be moist and soft, and make no painful pressure. At this point it may be well to add that, in order to diminish the chance of the plasters' stretching, when they have become moistened, the plaster should be cut in the direction of the warp, and not the woof, that is, in the long direction of the sheet. I wish also to add, that I have used the isinglass plaster, and other plasters, and I do not find any of them suit my purpose so well for this operation, as the common diachylon plaster.

If, within twelve to twenty-four hours after my first dressing, I observe any accumulation of milk, or of sordes of any kind, upon the surface of the lip, in the vicinity of the wound, I take pains to remove it carefully with a soft sponge, moistened with tepid water—the water containing a little castile-soap. This I do because I have observed that a great degree of the success in this operation depends on keeping the lip constantly so well cleaned, and free from excoriating material, as that no abrasions occur to interfere with the process of cicatrization. It is one of the most important means, also, in the prevention of erysipelas.

At each subsequent observation of the case, I readjust or renew more or less of the plasters, according as the exigencies of the case may seem to demand; and I never fail to observe again the condition of the wound as to cleanliness, nor, after the lapse of the second or third day, do I fail to note particularly the condition of the points at which the sutures have passed through the flesh; and if I observe anything like an appearance of ulceration, or of giving way, I not only cleanse it thoroughly with tepid water and soap, but I apply to it a weak solution of nitrate of silver, say gr. i. to 3 ij. water. If, on the second or third day, I observe that considerable inflammatory action, with more or less ulcerative action, has ensued, I may deem it advisable, as I have done in a *few* cases, to remove the sutures, and depend entirely upon the adhesive plasters. I wish it to be distinctly understood, however, that it is my general practice, now, to leave the sutures until the fifth, sixth, or seventh day; regarding them as important means of reserve, if, by any accident, the adhesive plasters should become suddenly loosened. I do not find that the little wounds, which are made in the flesh by the sutures, leave any permanent marks, if the operation is made early in life. This practice of renewing the adhesive plasters, I continue from day to day, for two or three weeks, and then they may be left off with safety. It will be seen that the employment of silver wire, or any metallic suture, in this mode of operating, would be attended with certain inconveniences, the ends of the wires being subjected to the pressure of the adhesive plasters; and as I have been sufficiently successful with silk sutures, and they are not liable to this particular objection, I see no reason why I should substitute anything for them.

When I say that of forty-nine cases, forty-six have united, I do not wish it to be understood that in all the cases the margins of the lip have united to the whole extent of the surfaces which have been made raw. In some few instances, the margins have given way above, within the alæ of the nostrils; but this has occurred particularly, I think, when the operation has been made late in life, the tissues then being less extensile, and when I have omitted to dissect up sufficiently freely the ala of the nose, upon that side upon which the fissure existed. These exceptions, however, have occurred only occasionally in the course of my practice. It has sometimes also happened that the lip has failed to unite, completely, at its lower margin, particularly on its vermilion border, and a slight fissure, or depression, has been the consequence; which I believe, however, when the operation has been performed early, has been overcome by the lapse of time; certainly it has in all those cases in which I have been permitted to see the patient after several years. But I know of no method by which this latter accident, viz. the giving way of the lower margin of the lip, can be more effectually avoided, than by my own—whether that method consists in the peculiar mode of incision upon the lower border, or in the addition of the supplementary stitch upon this border. I have tried them myself, and have seen them tried by others, and I prefer my own plan. It must not be forgotten that the lower stitch must be introduced precisely at the point of junction of the vermilion border with the integument. And it must not be forgotten that to secure it still further against giving way at this point, the protection afforded by the adhesive plaster is absolutely essential.

During the progress of the operation, and in the after treatment of the case, it is my custom to submit the child to no further confinement than is made by withdrawing the arms from the sleeves of the dress, placing them within the waist of the dress, and then putting the belt around the waist. This gives the child a certain freedom of motion of the hands, while it does not enable it to reach the face.

I have further to remark, that when I speak of the extraordinary success of my operation, I only refer to the matter of union of the opposing surfaces of the lip. Death has occurred from the operation in a certain number of cases, the precise number I am not now prepared to state; but in no instance has this taken place until after the union has been completed. It is certain, therefore, that none of these children have died of the immediate shock of the operation, since none have died earlier than the eighth or tenth day. None have died from the loss of blood. In those cases which I can now recollect, without reference to my tables, in which death has

taken place clearly traceable to the operation, the children have died either from diarrhœal affections, or, as in one instance, from an erysipelatous inflammation, which supervened as late as the fourteenth day. It must be remembered, also, that the majority of these infants are not robust. The very fact of an arrest of development, in my judgment, usually argues some constitutional defect, yet not invariably. In following, therefore, the histories of these children, I am not surprised to find that not many of them have survived to adult life.

I cannot now consider the double hare-lip of a simple character, or that in which the fissure does not extend through the alveoli; nor can I consider at this time the treatment which would be applicable to the various complications. My remarks have been based entirely upon the example of single hare-lip, which is now presented to you. It is true, however, that to a very great extent, the modes of procedure which have here been adopted, I have found applicable to all the varieties of double and complicated hare-lip. But of these, we shall have to speak at some future time.

The reporter has made the following analysis of these tables:

Of single and uncomplicated hare-lip operations, the number is 17; of single and complicated, the number is 22; of double and complicated, the number is 11. Total, 50, including the operation which has just been made. Averaged according to the ages they are as follows:

Age.	Single and uncomplicated.	Single and complicated.	Double and complicated.	Total.
From 7 days to 1 month.	None.	4	1	5
1 to 3 months	4	7	2	13
3 to 6 months	3	5	3	11
6 months to 1 year	2	1	2	5
1 to 2 years	None.	2	2	4
Over 2 years	7	3	2	12

Cases in which incision failed to unite:

Case 23: Child 2 months old; single and complicated. Operation made with hare-lip pins, and child left in the hands of another surgeon.

Case 35: Single and complicated; child 22 days old. The mother, an Irishwoman, living in a shanty; did not return to Dr. Hamilton until the fifth day after the operation, when the adhesive plasters were found to have become entirely loosened.

Case 32: Single and not complicated; feeble child, 7 months old. Incised the edges of the fissure with a bistoury, and did not leave a sufficiently wide margin for adhesion. Union had taken place on the fourth day; after which the child rapidly sank from diarrhœa, and died on the tenth day, the union which had occurred having given away through half its extent by the eighth day.

Of those who died, apparently directly or indirectly in consequence of the operation, the first was a child five months old, the operation having been made in midsummer. The child died on the eighth day, of diarrhœa and prostration. In the second case, the child was three months old; the operation was made again in midsummer; erysipelas, diarrhœa, and a general wasting supervened, and death occurred at the end of five weeks. The third case was a double complicated hare-lip, in child four weeks old; died at the end of two weeks of diarrhœa and general marasmus. The fourth case was of double complicated hare-lip, in a child five weeks and five days old; died on the fifteenth day, of general marasmus. The fifth case was single and not complicated; child seven months old; died on the tenth day, from exhaustion. This is case thirty-two, already mentioned as an example of partial failure.

Reports of Hospitals.

LONG ISLAND COLLEGE HOSPITAL.

A SERIES OF CASES ILLUSTRATING CARDIAC DISEASE.

SELECTED FROM PROF. FLINT'S CLINICS.

(Reported by O. C. SPARROW, M.D., Clinical Assistant to the Chair of Practical Medicine and Pathology.)

CASE II.—*Aortic Valvular Lesions: Mitral Direct Murmur implying no Lesions of the Mitral Valve.*

History.—Bridget P., æt. 46 years, a domestic, was admitted to hospital while suffering from intermitttent fever. She states that fifteen years ago she experienced a severe attack of articular rheumatism, involving most of the larger joints of the body; was confined to the bed for several weeks. She has not had an acute attack since, but frequently experiences rheumatic pains in different parts of her body. She complains of no urgent symptoms referable to the heart.

Physical Examination of Heart.—The impulse of the apex beat is in the fifth intercostal space, on a vertical line passing through the nipple. There is moderate enlargement of the organ, with evidence of predominant hypertrophy. On applying the stethoscope an aortic direct and aortic regurgitant murmur is heard. The latter has its maximum of intensity over the body of the organ. Over a circumscribed space near the apex, a feeble mitral direct murmur is distinctly appreciable.

Comments.—The chief point of interest belonging to this case relates to the occurrence of a mitral direct murmur, associated with aortic valvular lesions. This murmur has not unfrequently been observed in this connexion during life, in cases in which a post-mortem examination revealed no lesions of the mitral valve. Dr. Flint offered the following original explanation, which seems adequate to account for its occurrence under these circumstances: Following immediately upon the diastole of the ventricle, the regurgitant stream of blood begins to enter the cavity of the ventricle from the aorta, and since the systole of the auricle precedes by a brief interval that of the ventricle, the blood is also slowly trickling down, by force of gravity, through the auriculo-ventricular orifice. When, therefore, the auricle comes to contract, finding the cavity of the ventricle already partly filled, and the curtains of the mitral valve floating out loosely in the blood, they are thrown into a state of vibration, which produces the murmur. This explanation is rendered still further probable by observing the effect produced upon the curtains of the valve, by injecting water through the mitral orifice into the ventricle. They first float out loosely upon its surface, and are finally closed, when the cavity becomes filled.

CASE III.—*Valvular Lesions: Subacute Pneumonitis, Albuminuria.*

May 24.—*History.*—James Clohan, æt. 38 years. He dates back his illness three weeks. Supposes that he contracted a cold; had an annoying cough and expectoration; sputa sometimes streaked with blood. At the end of a week these symptoms had nearly subsided; when, without any apparent cause, the cough became much increased, accompanied by rusty sputa. Suffered lancinating pain in the side, which was most severe at the close of a deep inspiration. Felt chilly sensations. No marked febrile movement. His appetite has continued fair. Bowels regular. Has not been

confined to the bed. Never had articular rheumatism. Has suffered some deficiency of breath on exercise for several years.

Physical Examination.—Lungs.—Slight dulness over the posterior lobe of the right lung. Crepitant and subcrepitant râles. Exaggerated vocal and whispering resonance. Some subcrepitant râles are also heard on the left side, more marked behind than in front.

Heart.—The impulse of the apex beat occupies its normal situation. No enlargement exists. He presents two pretty loud murmurs, viz. mitral direct and aortic direct.

Urine.—This has a smoky color, and contains a considerable quantity of albumen. No microscopical examination was made.

℞. Syr. papaveris f ℥ ij.
S. Teaspoonful every five hours.

June 5.—Patient reports that since his last visit at the clinic he has had dropsy. This has chiefly disappeared, but there is slight pitting of the skin over the sternum and legs. His limbs have at times been œdematous before. The urine has a better color, but still contains albumen. His cough continues troublesome, and he complains that his appetite is becoming poor. Physical examination of the chest reveals about the same condition as at last visit.

℞. Potassii iodidi ʒ ij.
Tinct. gentianæ comp. f ℥ ij.
Syr. papaveris f ℥ i.
Aquæ puræ f ℥ j. M.
Sig. Teaspoonful every six hours.

Patient did not again return.

Comments.—We have already seen that valvular lesions, and most of all, mitral obstructive lesions, tend directly to induce congestion of the lungs, accompanied by various symptomatic events, as cough, dyspnœa, etc. This congestion predisposes to bronchitis, and even pneumonitis. Idiopathic bronchitis has little or no tendency to eventuate in the latter. In this case the effects of the obstructive lesions have obviously been propagated beyond the pulmonary organs, to the right side of the heart; reaching even to the systemic venous circulation. The venous trunks and branches, owing to the retarded flow of blood, have become engorged and distended, until, by a process of mere mechanical transudation, a portion of the blood serum has escaped through the coats of the vessels; and hence the dropsy. A point of special interest in this case relates to the albuminuria. In cases presenting cardiac dropsy, it is not uncommon for the urine to contain a trace of albumen, without implying the existence of any degenerative affection of the kidneys.

Instances, however, of the existence of genuine Bright's disease with organic affections of the heart, have been observed so frequently as to lead to the opinion that they sustain a causative relation to each other.

Assuming this to be true, the question arises—Which is the primary affection? The anatomical relations of the kidneys render them especially liable to passive congestion by obstructive lesions of the cardiac valves. Now, whether congestion thus occurring be sufficient to induce organic disease of the kidneys, or, on the other hand, whether the uræmic condition of the blood, incident to Bright's disease, by primarily determining endocarditis or pericarditis, may thus lay the foundation for the organic cardiac affection, are points which cannot be regarded as yet settled. It is not improbable that, in this case, the renal disease has contributed to produce the dropsy.

Progress of Medical Science.

INTERNAL STRANGULATION OF THE BOWEL BY A BAND, ASSOCIATED WITH A REDUCIBLE HERNIA, SUCCESSFULLY TREATED BY OPERATION.—Thomas Bryant, F.R.C.S., Assistant-Surgeon to Guy's Hospital, reports a case with the above caption in the *Lancet*. It was that of a gentleman, aged fifty-one, who had been ill for several days with symptoms of intestinal obstruction. The patient had been the subject of an inguinal hernia on the *right* side for twenty-five years, for which he had worn a truss; during that period the bowels had come down on several occasions, but it had only given pain on one—some six months previously. On the morning of December 28th, during the exertion of dragging up a tree, the hernia partially descended, but it was at once readily returned on the application of the hand; vomiting, however, soon appeared, and pain situated on the *right* side of the umbilicus. These symptoms continuing on the 29th and 30th, and increasing in severity, Dr. Wilkinson was sent for. A careful examination was then made, but no hernia was found; there was a large opening into the abdomen, but no swelling nor pain, even on deep pressure being made. On Dec. 31st (the third day) the symptoms becoming more severe, vomiting being fæcal, Dr. Wilkinson, who saw the necessity for an operation, called in the assistance of the author. The seat of the hernia was then examined, but no indications of anything wrong in these parts could be made out, yet marked symptoms of intestinal strangulation existed; pain in the abdomen was very severe; it was situated to the right of the umbilicus, and paroxysmal. Under those circumstances an exploratory operation in the region of the hernia was proposed, and power given by the patient to do whatever might be deemed the best. Chloroform was given, and the ring of the direct inguinal hernia exposed; no signs, however, of any strangulation of the bowel by the parts concerned in the hernia could be made out. A piece of omentum existed in the hernial sac, but no bowel. The finger could also be readily passed into the abdomen, and the neck of the sac was perfectly free. The bowel which came into view was, however, clearly strangulated, for it was of a bright cherry color, and œdematous. Under these circumstances the ring was enlarged upwards and the strangulated bowel drawn down; the finger of the author's right hand was then passed along the bowel, used as a guide, upwards into the abdomen towards the point of fixed pain. When it had been passed as far as it could go, and as much traction had been put upon the bowel as was deemed justifiable, a tight band was clearly felt. The abdominal incision was then enlarged, and the band, which was made tense by the finger, was carefully divided by a pair of scissors passed into the belly, its points being well pressed into the pulpy portion of the finger till the band was reached. The wound was then closed. On the third day the bowels acted naturally, and a rapid convalescence followed.

TREATMENT OF QUINSY SORE THROAT.—The *London Lancet* publishes an interesting report of the treatment of tonsillitis, adopted by physicians at the several metropolitan hospitals, from which we make a few extracts.—Dr. Anstie, Westminster Hospital, believes that in the suppuration variety two remedies only are of real value. If the case be seen early—i.e. within forty-eight hours of the occurrence of decided pain, before the swelling has become definite in form, and more especially if there has been no shivering and the febrile action is but slight, the application of strong local astringents is

almost certainly curative. The rough way of using this treatment is to order the patient to gargle every half hour with a solution of alum—twenty grains to the ounce. A more precise and effective use of the same astringent can be made by throwing such a solution, in the pulverised form, against the affected part. Another effective mode of local adstriction is the application of tincture of sesquichloride of iron on a sponge carried by a whalebone, which may be firmly pressed against the part. The other remedy besides local adstriction is the use, in suitable cases, of purgative medicine. If (and only in this case) there is reason to think the bowels are loaded, a brisk purge of any kind which does not produce exhausting serous exhalation will frequently give great and speedy relief.

If the disease has plainly gone on to the formation of pus, the above remedies are useless, and will only worry the patient. Our attention should then be directed, Dr. Anstie believes, to soothe pain, and to keep the swelling within bounds, while we also support the patient's strength. Hot fomentations and poultices should be applied around the throat, the patient should gently inhale the steam of boiling water, and he should be given strong beef-tea and small quantities of wine or brandy every four hours. In nine cases out of ten the pus may be left to find a natural opening, and only the occurrence of serious mechanical dyspnœa, or the appearance of a tendency to spreading of the suppuration, should induce us to use the lancet.

Dr. Wilson Fox (University College Hospital) treats ordinary cases of tonsillitis which present themselves within the first forty-eight hours of the invasion of the disease with a brisk mercurial cathartic, followed by a saline aperient draught. In cases which have even run a course of three or four days, the same plan is found by him to be beneficial, if the bowels have not been previously acted upon. Even in the early stages, unless the use of gargles gives much pain, he employs the following formula for this purpose:—Chlorate of potash, three drachms; nitrate of potash, half an ounce; glycerine, half an ounce; water, eight ounces. When seen early, this course is, in his experience, almost invariably sufficient to cut short the disease in a few days' time; and he scarcely recollects an instance where it has been adopted in which abscess has ensued. In cases of very severe swelling, he has occasionally found scarification useful; but he regards these as quite exceptional. If ulceration supervenes, either upon the tonsils or on the fauces, the solution of nitrate of silver, of the strength of fifteen grains to the ounce, is, in his opinion, the best remedy; and it may be advantageously applied to the tonsils, when suppuration is not present, in cases where the swelling lasts longer than five or six days. Dr. Fox strongly deprecates the use of the solid nitrate of silver in the early stages of the disease.

Dr. Clapton (St. Thomas's Hospital) recommends the usual depletory remedies, but objects to stimulating gargles in the early stages. When a patient has been the subject of repeated attacks of acute quinsy ending in suppuration, the plan of applying a liniment of thin extract of belladonna just below and behind the ramus of the jaw has been found a most excellent one, rapidly relieving the pain and intense irritation, and in some instances cutting short the progress of the disease almost at once.

In incipient sore throat, of whatever kind, Dr. Broadbent (St. Mary's Hospital) has for some time given small fragments of guaiacum resin—a piece to be kept in the mouth till dissolved, three or four times a day. The good effects have been very evident, more particularly in superficial inflammation of the mucous membrane; but tonsillitis has apparently been arrested, and in patients subject to quinsy attacks have been averted.

Dr. Headland (Charing-Cross Hospital) relies greatly upon chlorate of potash as a gargle and mild magnesian purges. None of the physicians think it necessary, except in extreme cases, to use the lancet.

Hereditary Predisposition in Phthisis.—As a general thing, pulmonary tuberculosis is more frequently transmitted to the younger than the older children of the family, and more commonly to the females than the males. In a table compiled from the Brompton Hospital Reports, London, I find that in one hundred cases of phthisis, the disease is transmitted by the father four times, and by the mother thirteen times. The reason for this may be found in the fact, that the females are more exposed to the same inducing causes as their maternal parent. I have known several families where the disease was confined exclusively to the females—the mother and daughters perishing with it, while the father and sons were exempt. We sometimes witness the same thing in cancer. I am acquainted with the history of a family, where for three generations nearly every female died with the malady, while there was not an example among the males.—*Dr. Dutcher, Med. and Surg. Reporter.*

A Diagnostic and Prognostic in Typhoid Fever.—The attention of Dr. E. H. Watts, of Gainesville, Ala. (Med. and Surg. Reporter), was, during 1850, directed to a peculiar discoloration in the fauces of patients suffering from typhoid fever. This spot was ovoid in form, varying in size from three-eighths to half an inch in length, and in breadth from one-fourth to three-eighths of an inch, and usually located just to the right and left of the uvula. It was usually observed from the fourth to the eighth day of the attack, making its appearance earlier if the attack was ushered in with severity—the shade of discoloration ranging from a little deeper pink than the adjoining mucous membrane to a deep purplish black. Its presence was proof of the nature of the disease. With a deeper shade of color, as observed from day to day, the disease was known to be progressing unfavorably; the gradual lightening up of the tint indicated a restoration to health; fading away entirely during convalescence, and becoming a very deep purple in all the cases that terminated unfavorably. Seventeen years more of observation have led Dr. W. to lay great stress on its value in the diagnosis and prognosis of typhoid fever.

When One Eye only is Blind, is it Prudent to Attempt to Restore Sight while the other remains perfect?—Mr. Haynes Walton, speaking from his own experience, says, "Yes." He continues: "I should be deterred from operating only by the probability of the eye being too much damaged, to give that amount of sight which is known as useful sight, on which point much discrimination and a long familiarity with ophthalmic surgery are imperative. I have selected those cases only in which I was as sure as I could be that the fundus of the eye was sound, and the retina unimpaired, and the other conditions such as would insure the best amount of sight to be derived from such an operation, *i. e.* making a false pupil. I am certain, therefore, from the results of practice, of the advisability in certain cases of making a false pupil when one eye is sound. Confusion of vision does not and is not likely to result. In *coloboma iridis* in one eye, no confusion follows." Mr. Walton then details cases of monocular cataract in which he has operated with success and with great benefit to the patient, as well as some of opacity of the cornea, also monocular, where he did iridectomy.—*Med. Times and Gazette.*

THE DISCOVERER OF ANÆSTHESIA.

WHEN any brilliant discovery has been made, it is natural for a number of aspiring and ambitious individuals to claim the credit of it. This has eminently been the case with that of anæsthesia. No sooner was it fairly established that surgical operations could be performed without pain, than the attention of the profession was directed to the settlement of the respective claims of Wells, Morton, and Jackson, to the credit of conferring this priceless boon upon humanity. The controversy soon, however, became so lengthy and complicated that the majority of those who desired to see fair play became wearied and disheartened, and were ultimately unable, in the absence of testimony that could be relied upon, to come to any conclusion whatever. It was evident that the honor belonged to one of the three, but to whom in particular, there did not appear to be any great chance of determining. A sufficient time has now elapsed since the controversy alluded to, to enable all those who have not come to a conclusion upon the subject, to examine the facts of the case in the calm and unprejudiced manner which should characterize a search after truth. In such an agreeable task they have a very timely aid in a report by the Hon. Truman Smith, recently published. We venture to say that the facts which have been brought to light by this distinguished gentleman, will be found to present the question in its true aspect. The argument is a long and sound one, and serves to add not a little to the well earned reputation which the Senator has enjoyed for rare legal attainments. The bulk of the volume has already appeared in the columns of the Philadelphia *Medical and Surgical Reporter*, at the time when the pretended claims of Morton were being actively canvassed at Washington before the Congressional Committee; but the subject is now invested with a new importance in consideration of the signal defeat of the said Morton's claims, and the lapse of that amount of time which allows of the cooling down of all prejudice. The writer of the volume has spared no pains in accurately and thoroughly investigating his subject, and were we to follow him in the different steps which he has found necessary to take in order to enable him to point out the true relation of unquestionable facts sifted of their complications on the question at issue, we should consume unnecessarily much of that space which must be otherwise appropriated. We will then content ourselves with the simple account of the discovery of anæsthesia, based upon the facts which the honorable gentleman has given us, and leave the remainder of the work to the perusal of such of our readers who may wish to satisfy themselves concerning the foundations for the statements here made.

The discovery is dated as far back as the tenth of December, 1844. On the evening of that day, Dr. Horace Wells, a surgeon-dentist of Hartford, attended in that city a chemical lecture by Mr. G. Q. Colton, during, or after which, the said Colton administered to Dr. Wells, Mr. Cooley, and several others, some nitrous oxide gas. Mr. Cooley, while under its influence, became much excited, and in performing sundry evolutions contused and abraded both his shins. On recovering his self-possession he was interrogated by Wells as to the amount of pain he had suffered from the injuries received. In reply Cooley stated that he was not conscious of any such occurrence and was surprised, on pulling up his pants, to see a profusion of blood. Wells immediately turned to a friend and expressed his belief, "that a man could by inhaling the gas render himself so insensible that he could have a tooth extracted without pain." While escorting his wife home, he reiterated an expression of the same belief, and again reiterated it to a brother dentist and particular friend, on whom he called the same evening to canvass the subject. Having spent some time in considering the matter, Dr. Wells declared it to be his purpose to take the gas the next day and have a defective tooth (a large molar) extracted, and thus test the correctness of his theory. Accordingly the following day, Wells called on Colton, and desired the latter to take a bag of the gas over to the office of the dentist alluded to. On arriving at their place of destination, Wells placed himself in the operating-chair, was anæsthetized by Colton, and the tooth extracted. On recovering consciousness, the subject of the operation, in his satisfaction at the result, exclaimed: "A new era in tooth-pulling! It did not hurt me more than the prick of a pin!"

This, according to the testimony we have before us, was the first operation performed with an anæsthetic, and to the late Dr. Horace Wells belongs the sole credit of first conceiving the possibility and practicability of killing pain by its administration.

It was not until the 30th of September, 1846, that Morton made a test of the anæsthetic properties of sulphuric ether, at the suggestion of Dr. Charles T. Jackson, having, as it would appear, previously obtained whatever he knew of the practicability of anæsthesia from Wells himself, with whom he had been more or less intimately associated.

We have endeavored to present the simple facts of the case so clearly and satisfactorily proved by Mr. Smith, with the sole desire of doing our part in giving publicity to a matter which is of the deepest concern to every lover of justice; and to those who may have failed to convince themselves of the impartiality of the award of this great discovery to Dr. Wells, we would commend for their diligent perusal the masterly argument of the Hon. Truman Smith.

It is with extreme satisfaction that we notice the commencement of a move in the right quarter towards checking the prevalent practice of producing and procuring abortion. So deeply rooted has become the vice, that every influence which religion, morality, and law can bring to bear is now urgently needed. Medicine has long ago taken the lead; Christianity followed with its appeals; and now law brings up the van with an earnestness for the work which almost entitles it to forgiveness for its former stubborn apathy. The State of Rhode Island deserves the honor of the initiative in this latter respect, and the following enactment is an evidence of an enlightened legislation which does credit not only to the source from which it emanates, but the age in which we live. We quote the following act referring to the subject in question, passed at the January Session of the General Assembly, 1867:

It is enacted by the General Assembly as follows:

Sec. 1. Every person who shall be convicted of wilfully administering to any pregnant woman, or to any woman supposed by such person to be pregnant, or of advising or prescribing for such woman, or causing to be taken by her, anything whatever, or shall employ any means whatever, with intent thereby to procure the miscarriage of such woman, or of aiding and assisting therein, or by counselling and procuring the same, unless the same is necessary to preserve her life, shall, if the woman die in consequence thereof, be imprisoned not exceeding twenty years nor less than five years; and if she do not die in consequence thereof, shall be imprisoned not exceeding seven years nor less than one year: *Provided*, that the woman whose miscarriage shall have been caused or attempted, shall not be liable to the penalties prescribed by this section.

Sec. 2. Any person who shall be indicted for the murder of any infant child, or of any pregnant woman, or of any woman supposed by such person to be or to have been pregnant, may also be charged in the same indictment with any or all the offences mentioned in the preceding section, and if upon the trial the jury shall acquit such person on the charge of murder, and find him guilty of the other offences or either of them, judgment and sentence may be awarded against him accordingly.

Sec. 3. Whoever knowingly advertises, prints, publishes, distributes, or circulates, or knowingly causes to be advertised, printed, published, distributed, or circulated, any pamphlet, printed paper, book, newspaper, notice, advertisement, or reference, containing words or language giving or conveying any notice, hint, or reference to any person, or to the name of any person, real or fictitious, from whom, or to any place, house, shop, or office, where anything whatever, or any instrument or means whatever, or any advice, direction, information, or knowledge may be obtained for the purpose of causing or procuring the miscarriage of any pregnant woman, shall be imprisoned not exceeding three years.

Sec. 4. All acts and parts of acts inconsistent herewith, are hereby repealed; *provided, however*, that nothing in this act contained shall in any wise affect any complaint or indictment now pending, or that may hereafter be made or found for any offence committed before the passage of this act, against the provisions, or any of them, of an act in addition to chapter 212, title XXX., of the revised statutes, "of offences against the person," passed at the January session, 1861.

Sec. 5. This act shall take effect on and after its passage.

Another death, occasioned by the careless compounding of a prescription, is announced by the daily papers. It seems that a physician had prescribed for a patient in Brooklyn, suffering from neuralgia, a drachm of quinine and one grain of nux vomica, to be divided in fifteen pills. This was properly made up by an apothecary, and everything went on well. Having occasion to use some more of the same medicine a messenger was sent to a different store, owned however by the proprietor of the first. The clerk of the second store sent to the first store for a copy of the recipe, but instead thereof the copyist made the egregious and unpardonable blunder of transposing the quantities, so that the pill-mass, when compounded by the second party, contained a *drachm* of nux vomica and one grain of quinine. The unfortunate patient swallowed but two doses, and died in convulsions a few hours afterwards. It is not difficult to see where the blame for this transaction rests. The mistake was not made by the physician, for the writing was intelligible enough to enable the clerk of the first store to follow the directions; but the carelessness of the copyist, and the stupidity of the subsequent compounder, are, to say the least, r emarkable, and deserve that severe punishment which will probably be respectively meted out to them.

Reviews.

Transactions of the American Medical Association. Vol. xvii. Philadelphia. 8vo. pp. 713.

This yearly volume comes to us in its usual good style, and has the double merit of being much reduced in bulk, and at the same time containing many valuable contributions. The report of the annual meeting was so fully given in our columns that it would be hardly more than a reiteration to review the contents in detail. We were enabled to present, at the time we published the transactions of the body, an abstract of all the important papers that were read at the said session, and our readers have had long ago an idea of the worth of the volume. We cannot be expected to do more than refresh the minds of those who have not already become the possessors of this publication as to some of the more important contributions which it contains. They may be summed up in the following catalogue: "On the Relations which Electricity sustains to the Cause of Disease," by S. Littell, M.D., Philadelphia; "Report of Committee on Disinfectants;" "Causes and Pathology

of Pyæmia," by J. J. Woodward, M.D., U.S.A.; "The Clamp-Shield," by Prof. H. R. Storer, of Boston; "Paralysis of Vocal Cords with Aphonia," by J. Solis Cohen, of Philadelphia; "Luxation of Femur in Ischiatic Notch, of Nine Months' Standing," by L. A. Sayre, M.D.; "Original Instrument for the Performance of Lithotomy," by Prof. A. C. Post, New York; "Report on Diphtheria," by H. D. Holton, of Vt.; "Report on Spotted Fever," by J. J. Levick, Philadelphia; "On Etiology and Pathology of Epidemic Erysipelas," by Prof. N. S. Davis, M.D., Chicago; "Medical Literature," by Prof. C. A. Lee; "Medical Ethics of Specialties," by Prof. W. Hooker, New Haven; "Treatment of Angular Curvature of Spine," by Benjamin Lee, M.D., Philadelphia; and "Digitalin," by Prof. S. R. Percy, New York (Prize Essay). Altogether, the volume compares creditably with any of its predecessors; its typographical execution is admirable, and its illustrations very passable.

TRANSACTIONS OF THE VERMONT MEDICAL SOCIETY, for the year 1865. R. S. Styles, Burlington. Pp. 61.

THE Address of the President, Dr. O. F. Fassett, of St. Alban's, is an interesting survey of the mutual relations existing between the people and the profession, and the rightful demands of the profession upon both people and the government. To do the subject justice would require a quotation at length, a pleasure we are obliged to forego. "Statistics of Diphtheria in Vermont. By H. F. Stephens, M.D." In 1857, two years after the publication of M. Bretonneau's dissertation, a few cases are borne upon the registration report of the State as deaths from "Disease of Throat." Many deaths were then very likely to have been incorrectly credited to scarlatina, which prevailed very extensively in every county. It was not, however, until the succeeding year, that diphtheria was definitively assigned as a cause of death. Fourteen cases were then given, but scarlatina also increased in fatality. In 1859, 1860, 1861, and 1862, the mortality from diphtheria is quoted successively as 60, 212, 441, and 818, making a gradation of 2, 6, 11, and 18 per cent. The compiler is, however, as yet unable to draw conclusions, since the data are too limited. "The Physiological Properties and Therapeutic Action of Veratrum Viride. By L. C. Butler, M.D." (of Essex). This article, by the Secretary of the Society, gives much valuable information in a reasonable compass, and presents us with a rose-colored view of its general applicability in therapeutics. It is, however, but just to add that all the statements are well fortified by facts. "Case of Dropsy. By Lemuel Richmond, M.D. (of Derby)." The points of the case are paracentesis performed sixty-eight times, and 2383 lbs. taken in seventeen months and twelve days. "One day previous to and one day after the operation she would seem somewhat prostrated, otherwise generally very comfortable and able to go about, sometimes even to visit her neighbors. Notwithstanding the rapid accumulation in her case, there was but a short time that she seemed troubled with thirst. A post-mortem examination discovered an omental cake, a broad band extending from this to the fundus of the uterus, to which it was attached." "Criminal Abortion. By William McCollem, M.D. (of Woodstock)," an earnest, able paper, is followed by another on "Cerebro-Spinal Meningitis, by B. F. Ketchum, M.D. (of Brattleboro')." Dr. K. had seen some thirty cases in his locality, where the disease appeared about January 1, 1864. Having concluded that the feeble pulse was dependent upon the congested condition of the nervous centres, and that a vital organ was involved, he determined upon venesection, as being the only rational remedy. He claims that it should be performed early in the disease, and the blood let run "in a full stream from a large opening." Cupping and leeching are worse than temporizing expedients; and "venesection, practised in advanced stages of the disease, or after effusion had taken place, did harm, as then we have real debility." "Memoir of Dr. N. W. Fairchild, by H. F. Stevens, M.D. (of St. Alban's)," is next in order. "Morbus Coxarius, by Benjamin Fairchild, M.D. (of Milton), (communicated by the Chittenden County Medical Society)," is a practical paper, from which many useful hints may be derived. The last contribution is from the pen of Dr. C. P. Frost (late Surgeon of the Board of Enrolment, Second District, Vermont), and being relative to the draft during 1863, 1864, and 1865, is statistical in character.

When we remember that the present constitutes the first published compilation of the "Transactions," we cannot but admire the enterprise of the Society in presenting so creditable an issue to their brethren, and, above all, would we commend that rare self-denial which has in no instance allowed the work to go beyond the material.

OBSTETRICS: THE SCIENCE AND THE ART. By CHARLES D. MEIGS, M.D., lately Professor of Midwifery and the Diseases of Women and Children, in Jefferson Medical College at Philadelphia, and one of the Physicians to the Lying-In Department of Pennsylvania Hospital, etc., etc. Fifth edition. Revised; with one hundred and thirty illustrations. Philadelphia: Henry C. Lea. 1867. 8vo., pp. 754.

PROF. MEIGS'S work upon Obstetrics has been before the public for the past thirty years, and since its first publication in 1838, as a modest volume of two or three hundred pages, it has kept its ground as an authority. It has passed through four editions, and the fifth is just issued, after having suffered a thorough revision by the author. Although not much new matter has been introduced, several parts of the work have been virtually re-written, and the results of this labor are given us with the sad announcement that this will probably be the last occasion that the writer will have of improving his book. The result of this endeavor of our author to give the finishing touches to his popular treatise, has been to make it of particular value to the student and younger physician by the embodiment of a vast number of practical hints and useful suggestions, gained by a very long and large clinical experience. To such as may not be acquainted with the merits of the work through previous editions, we would confidently recommend it as a most reliable, useful, practical one for the student and younger physician, as many of those very necessary details are dwelt upon which may be looked for in other treatises in vain. The style is attractive, concise, and earnest; and the reader is all the time made conscious that his teacher has but one object in view, that of instruction, and that no effort is spared by him to faithfully and conscientiously discharge such a duty.

CODE OF MEDICAL ETHICS, ADOPTED BY THE AMERICAN MEDICAL ASSOCIATION. Revised to date. New York: W. Wood & Co., 61 Walker st. 1867. 18mo. pp. 39.

THE publishers of this little book have anticipated a want long felt by the profession—that of having in a convenient shape the Code of Medical Ethics. There is now no excuse for any delinquent brother being unacquainted with the rules which should govern his actions; and if any of our readers should find any such who refuses to be convinced of the error of his ways, he should purchase a copy and present him with the same.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, FEBRUARY 27, 1867.

DR. H. B. SANDS, President, in the Chair.

DR. POST exhibited a hygroma of the neck which he had treated by excision. The patient was a woman twenty years of age, who first noticed a painless enlargement on the side of the neck, about two years ago. The history was the ordinary one of a cystic tumor in that locality. The mass was first punctured, but the sac soon filled again, when the Doctor determined to exsect it, which he did without any great difficulty. He remarked that this was the first operation of the sort which he had done, and from the good results in this instance he was encouraged to generally adopt the practice.

DR. SANDS asked if Dr. Post had been in the habit of injecting the pure tincture of iodine into these cysts, as recommended by Syme.

DR. POST had no distinct recollection of so doing.

DR. PEUGNET presented a heart and kidneys removed from a patient, who first showed symptoms of cardiac disease on the first of February, 1864. It first commenced with an attack of dyspnœa, ending in syncope, which lasted for several hours. On examination he found hypertrophy of the heart, with emphysema of the upper lobe of the left lung. At that time there was no sign of any renal trouble. The patient had two or three attacks of syncope from that time until last spring, when he took a trip to Europe. While abroad he consulted several distinguished physicians, who virtually substantiated the diagnosis of his attending physician. When the patient returned about the middle of last October, Dr. P. not only found that the hypertrophy had very much increased, but that œdema of both lungs was superadded to emphysema. Professor Clark was then called in consultation, and an examination of the urine being then made, resulted in discovering evidences of Bright's disease. From that time, however, no traces of disease of the kidneys were discovered, notwithstanding repeated examinations were made for that purpose. There were no murmurs detected during life, although the autopsy showed atheromatous deposits around both the mitral and aortic valves, there being besides a slight rupture in one of the latter. The lungs were found to be extensively emphysematous, and the liver in the first stage of fatty degeneration.

In answer to a question from Dr. Noyes, he stated that the urine had been found deficient in urea upon two different occasions.

DR. DRAPER remarked that a well marked contraction of the aorta, which existed in the specimen, was of itself sufficient cause of the hypertrophy.

I. CARIES OF SPINE CAUSING ABSCESS.—DEATH FROM ASTHMA MILLARI. II. CHEMICAL SOLUTION OF URINARY CALCULI.

DR. BAUER presented a specimen of fracture of the first dorsal vertebra, accompanied with the following history :—

The little patient was but three years and nine months old. She belonged to a healthy family. About four months ago she met with a fall from a chair against a wall, in such a way as to force her head forward upon the chest. Since then she has suffered severe pain at the neck, and general attenuation with the usual constitutional disturbances. I saw the patient for the first time on the 14th of January. The cervical portion of the spine was bent forward, and the head strongly reclined. At the cervico-thoracic portion of the spine there was a marked prominence of the several spinous processes, of which the first dorsal projected furthest. While carefully proceeding with the examination the patient was suddenly attacked with asthma Millari, and so intense and lasting was the paroxysm that I feared instantaneous death, the respiration being totally suspended for at least fifteen seconds, her face becoming thoroughly cyanotic. I did not carry the examination further, being satisfied that there was a structural lesion of the spine, with probable formation of abscess and pressure upon the recurrent nerve. The mother told me that these paroxysms had been quite frequent of late, but that the present one was in her estimation the severest. The treatment could be but palliative. I ordered a water bed, the recumbent posture, and very careful handling. My apprehension that the child would die from the repetition of such paroxysms was soon fulfilled. After a few light paroxysms she succumbed to a very violent attack on the 19th inst.

Fortunately an autopsy was permitted. I found an abscess in front of the spine, commencing at the fourth cervical and terminating at the fourth thoracic vertebra. The anterior wall of this rather narrow abscess was formed of the periosteum and the longitudinal ligament, and encroached materially upon the œsophagus. The diseased portion of the spine being removed, is now exhibited to the society. The specimen consists of the fragment of the seventh cervical, and the second and third thoracic vertebræ, the next superior and inferior vertebræ being substantially healthy although slightly corroded. The bodies of last cervical and first thoracic vertebræ are entirely destroyed up to the place where the bodies join the respective arches. Of the second thoracic, a large portion of the body has disappeared, whereas the body of the third thoracic has been but slightly affected. The first and second ribs on each side have lost their respective vertebral insertions. The spinal cord is deprived of its bony protection through the destruction of the two vertebral bodies. There is a small sequestrum remaining, obviously belonging to the seventh cervical. It is surprising that under these circumstances no paralysis has supervened. The matter that filled the abscess was rather thin, but presented otherwise the ordinary attributes. The rapid destruction of the vertebral bodies in comparatively so short a time, scarcely a vestige being left, is a matter of great pathological interest. Next in interest is the question of causation. There appeared to be nothing in the child of a tubercular diathesis, either inherited or acquired, nor have I found any morbid substance that could possibly be confounded with tubercular deposit. On the other hand, it is known that the child met with a serious accident, which was moreover of a description to cause, if not a fracture of the vertebral body, at least a crushing. And lastly, it is substantiated that the patient was entirely well until the accident occurred, and since then has been suffering from symptoms entirely local in origin. I consider myself, therefore, justified in assuming that the specimen represents one of those numerous cases of caries and deformity of the spinal column that are of a strictly traumatic origin.

He also presented a few urinary calculi, of which the largest weighed a little over two drachms, and gave the following account of the patient from whom they were removed in successive operations. The subject was a child three and a half years of age. The first operation was the bilateral one, and due care was used to clean out the bladder and urethra afterwards. The recovery from the operation was rapid and satisfactory. A fortnight afterwards, however, new signs of the existence of lithiasis began to show themselves. Interfe-

rence was deferred for four months, when the sufferings of the child becoming so intense, the old wound having opened, and fistulous connexions having formed between the perineum and bladder, there was no alternative left but to repeat the former operation, so as to remove calculi and likewise close up the fistulous track. On that occasion several small calculi were taken away. Dr. B. had previously carefully examined the urine, and had convinced himself that it was very much saturated with urates and phosphates. About five or six weeks after the second operation, there were new signs of stone; and it being evident that the circumstances of the case forbade the performance of a third operation, he resolved to treat the case with chemical reagents, after removing such calculi as had become impacted about that time into the urethra. When he experimented with fragments of the calculi, with a solution of one part of nitric acid in eight of water, he discovered that he had no difficulty in almost entirely dissolving them, there being left nothing but a soft pulp. Under the impression that the bladder could easily void such masses, he commenced the injection of the solution into the cavity of that organ. The liquid was kept in the bladder for two or three hours at a time, by means of an india-rubber ring enveloping the end of the penis. He watched the effects of this treatment very carefully in the beginning, and soon felt assured that it could be carried on with impunity. Pulpy masses were soon after discharged, and finally even these disappeared at the end of a period of sixteen months, during the whole of which time the injections were continued. It is proper to state that, in the mean time, the patient took internally the nitro-muriatic acid.

EXTENSION OF INFLAMMATION FROM A DEEP CERVICAL ABSCESS TO THE BRAIN.

Dr. Noyes presented a brain and section of the petrous portion of the temporal bone, removed from a patient in the Charity Hospital. On the 15th of February his attention was directed to a female who had been admitted on account of severe trouble of the right ear. She had been an inmate of the institution a couple of days, but the history of her case was extremely imperfect. All that was known of her was that she had suffered from a severe pain on the side of her head for the previous month. Although he was able to make only a very hasty inspection, the following peculiarities were observed:—A large swelling over the angle of the jaw, head turned to the opposite side, intelligence very much diminished though not abolished, no general paralysis of sensation or motion. The account given of the case looked towards the probability of there being caries of the petrous portion of the temporal bone, with meningitis supervening. Three days after the patient was again seen, when the symptoms of disease of the brain were even more pronounced than on the previous visit. The right eye was then carefully examined. The pupil had its normal reaction to light, the orbicular muscle preserved its functions, although the facial nerve was paralysed. This latter fact was, however, noticed at the first visit. Examination with the ophthalmoscope showed pulsation of the retinal veins with diminished size of the arteries, and absence of capillary hyperæmia of the nerve. No evidences of actual disease of the ear were found. The membrana tympani was normal in appearance. The swelling over the angle of the jaw was opened, and discharged a small quantity of fœtid pus. A considerable portion of the ramus of the jaw-bone was denuded and dead.

The general symptoms, at this time, were extreme stupor; not, however, amounting to coma. The pulse was about 100, respiration 20, the other phenomena being as already described. She died within a few hours after the examination. The diagnosis was that the abscess, which was deeply situated in the tissues of the neck, had excited inflammation of the brain; but how this was done, was left to the autopsy to determine.

Autopsy.—The autopsy showed the following facts: That there was very considerable turgescence of the meninges of the brain. Upon removing the dura mater, pus was found upon the side and anterior portion of the right hemisphere, the left hemisphere being free from any exudation. On removing the brain, pus extended down over the right hemisphere to the base of the brain, occupying the whole inferior surface of the organ, but concentrated more particularly about the middle fossa of the right side. The dura mater was readily separated from the base of the skull, but there was no pus between it and the bone. An incision was carried along the line and angle of the jaw; the whole bone, when exposed, was found surrounded with suppuration, which had denuded it of its periosteum nearly down to the dental foramen. The joint was completely destroyed, and disarticulation was of course effected with perfect ease. The cavity of the abscess which surrounded the joint was so situated as to lie above, in contact with the base of the skull, within the cervical vertebræ and pressing upon the pharynx, and externally covered with the sterno-cleido-mastoid muscle; its whole capacity being about the size of a pullet's egg. It was at first fancied that before death there was a communication with the brain through the spheno-maxillary fossa, but this supposition was overthrown by the absence of protrusion of the eyes and œdema of the lids. A careful examination of the upper part of the abscess with the probe, discovered that the foramina for the tranmission of the nerves, particularly the foramen ovale and foramen spinosum, had their margins denuded and roughened; and, furthermore, the basilar process of the occipital bone presented a very injected and succulent appearance. On examining the petrous portion of the temporal bone, and making a section of it, the external auditory canal was fortunately laid open, and the cavity of the middle ear. Both the bone and the auditory apparatus were found perfectly healthy. A further preparation of this specimen, by Dr. Weir, gave a very satisfactory exposition of the anatomy of the internal ear. The case was a very interesting one, as proving an unusual course for the extension of inflammation from a deep cervical abscess to the cranial cavity.

MALIGNANT DISEASE OF THE DURA MATER.

Dr. Draper presented a specimen of malignant disease of the dura mater. The patient from whom the specimen was taken was a young Irishman, fifteen years of age, who was admitted to the hospital on the 3d of January. He stated that he had been in good health until last spring, when he had a severe attack of fever and ague. He recovered from that, however, and continued at his work until about two months before he entered the hospital, when he began to suffer severely from pains in the lower part of the back, extending around the abdomen in front, and down the thighs. These pains were aggravated by movement, and were ascribed to rheumatism. He however kept at his employment until ten days before his admission, when he was obliged to give up and take to his bed. He walked into the hospital, although his gait was somewhat unsteady, and he leaned considerably forward. When Dr. Draper saw him on the 3d of January, he was suffering extreme pain in the lower part of the back, extending down towards the pubes in front, and the sciatic nerves posteriorly. The pain was aggravated by movements, and also by pressure; there was tenderness over the lower dorsal and lumbar vertebræ, and on the left side there appeared to

be some swelling and greater tenderness. His general condition was feeble, the pulse was rapid, and the skin hot. The first impression was that he had, in all probability, a lumbar abscess; but as there was an inability to detect fluctuation in the swelling on the left of the spine, no positive opinion could be arrived at. He was obliged to sit up in bed, and every movement was accompanied by pain, which was much aggravated at night. As a consequence he was kept under the influence of morphine, hypodermically administered, during the whole of his illness. On the third day after his admission, it was observed that he had retention of urine, and on examination there was absolute paralysis of motion, and very considerable anæsthesia. Although the bladder was paralysed, the sphincters retained their integrity. There was a slight amount of priapism noticed at this time. This condition of absolute paralysis of motion of the lower extremities and anæsthesia continued about a week, when the anæsthesia was lost, and the patient became extremely hyperæsthetic, intolerant of the slightest touch upon the lower extremities. There were no spasms of the lower extremities, the reflex function being entirely abolished. He continued in this condition until the 17th of February, when he died.

The only symptom which indicated any change in his condition was that after the paralysis had continued about a week, the rectal sphincter gave way. The vesical sphincter continued good until death. His condition grew worse, his perspiration profuse at night, pulse feeble and rapid, and emaciation extreme. Within four days after there was paralysis of motion, a large bed-sore formed upon the sacrum, and the other prominences were threatened with the same condition. It was necessary, on account of this, to protect him with great care with oakum ring-pads; and with the exception of the large bed-sores on the sacrum, and others which followed over the trochanters, he escaped further serious trouble in this respect.

The autopsy was made twenty-four hours after death. The emaciation was extreme. The rigor mortis was not very considerable. The lungs were found to be healthy. This is an important fact; as, after admission, his chest was examined, and there was found dulness, a prolonged expiration, and increased vocal resonance. The kidneys were found diseased. The surface of one of these organs was marked with ill-defined yellowish deposits, infiltrated in the cortical substance. Several of the mesenteric glands were very much enlarged, and were the seats of medullary cancer.

The cavity of the spine was very carefully opened, and the cord removed from the third dorsal vertebra down. On opening the cavity, the membranes were found below the dorso-lumbar enlargement, and very much distended with fluid; and on slitting up the membranes, this fluid was found perfectly clear and free from any lymph or purulent admixture. On examining the membranes a deposit was found, extending from the point of emergence of the tenth dorsal to the emergence of the first lumbar, resembling lymph. There was no marked injection of the membranes, the peritoneal arachnoid was free from turgescence, and the visceral arachnoid was scarcely more injected than normal. The pia mater was nearly natural; the consistence of the cord was normal, both above and beneath the deposit. On dissecting the areolar tissue about the deposit, it was found that it had a very well defined margin, and on microscopic examination, there was an entire absence of the elements of inflammatory exudation; but their other elements consisted entirely of nuclei, granular nucleated cells, and a small amount of connective tissue. These nuclei were a little larger than pus-cells, being about the two-thousandth of an inch in diameter. The same elements were found in the enlarged mesenteric glands. The substance of the cord was surrounded by this deposit, and many of the ganglionic cells were very granular.

Dr. Loomis could not see how there could have been dulness on percussion, increased vocal resonance, and prolonged expiration, without some deposit in the lung to explain it.

Dr. Krackowizer remarked that in shallow, hurried respiration all the physical signs of absence of air were often given.

Dr. Loomis could conceive it possible that the respiratory motions should modify the sounds heard on auscultation, but they could not, in his opinion, change the vesicular character of the respiratory murmur. In order to give all the physical signs referred to by Dr. Draper, a solidification by effusion must take place.

Dr. Draper remarked that the diagnosis, at first, had been tubercular deposit in the lung, with the same disease in the spine. The autopsy was the only thing that decided against it. The patient was carefully examined, and the physical signs were unmistakable. As there proved to be an absence of disease of the lung, he was forced to conclude that the phenomena were due to other causes, the most likely one of which was imperfect and shallow respiration. There was an absence of the usual amount of air to give the lung tissue its normal physical signs.

Dr. Loomis contended that there must be some other cause at the bottom, as, for instance, an effusion of some kind. This might have been a temporary affair, and at the time of death left the lung in a healthy condition.

Dr. Krackowizer stated that simple congestion of the lung, *without* effusion, would produce many, if not all, the signs of solidification. The same condition was induced by the absence of the normal quantity of air in the lungs. He had proved this in those cases of croup which had given him reason at first to suspect a complication of pneumonia. He did not believe that any amount of congestion could alter the respiratory sounds to give evidences of even a slight degree of congestion unless there was some effusion.

Dr. Bibbins asked if there was not dulness on percussion in the hypostatic congestion of typhoid fever.

Dr. Krackowizer remarked that when that did exist there was always effusion

Dr. Weir presented the ulna of a boy who had sufferred from osteo-myelitis of that bone, the result of a blow received by a falling ladder. The patient entered St. Luke's Hospital on the 30th of January, three weeks after the receipt of the injury. Two days after admission a swelling formed in the situation of the injury, which, being opened, discharged about two ounces of pus. This relieved him somewhat from the pain which he had previously suffered, and he went on well enough for forty-eight hours, when he began to suffer from great nervous excitement and prostration; the pulse was feeble and quick; there was sinking of the eyes, together with other phenomena marking great constitutional disturbance. At the end of twenty-four hours a circumscribed pneumonia was found just below the scapula, as well as a swelling near the elbow-joint of the opposite arm and considerable pain in the calf of the right leg, with tenderness and redness along the femoral vessels. The patient's condition kept about the same for three days after this, when a large abscess was noticed over the right hip-joint, communicating with it and extending some distance down the thigh-bone. The swelling in the right forearm did not augment rapidly. Further than this, there was nothing noticeable, with the exception that there were no chills, and, with the exception of two days preceding his

death, no sweating. The treatment consisted of sulphite of soda in 3 ii. doses three times a day. The temperature throughout ranged from 104° to 105°. An examination of the bone after its removal showed its medullary tissue reddened, except at the central portion of the canal. The redness was most intense near the elbow-joint, where there was an abscess of the bone, walled in by adventitious tissue. The examination of the diseased portions by the microscope showed the usual pathological characters. The wrist-joint not involved.

Dr. Wooster Beach, Jr., presented two hearts, taken respectively from men who had died suddenly. One was the seat of fatty degeneration, and the other had an aneurism above the aortic valves, causing fatal pericarditis. The previous histories of the patients were unknown.

TUMOR OF THE BRAIN.

Dr. Loomis exhibited a specimen of tumor of the brain, taken from a man thirty-five years of age. The patient was admitted to Bellevue Hospital on the 26th of January, 1867, and stated that some two years before he began to be seized with attacks of dizziness, which would last for a moment, pass off, and be followed for a short time with twinging of the facial muscles of the left side. These muscles afterwards became paralysed. In October, 1866, he was suddenly seized with hemiplegia, which lasted a week or ten days and then disappeared, the facial paralysis continuing, however, until his death. When admitted to the hospital no evidence of paralysis, except in the facial muscles. *He had the ordinary amount of intelligence of a person of his class*, and seemed to be in comparatively good health. After he had been in the hospital for a short time he became totally blind, and in a week or so began to grow stupid and finally died of coma.

At the autopsy a tumor was found in the posterior lobe of the left cerebrum, embracing very nearly the whole of that organ. It seemed to be attached firmly to the membranes of the brain, the dura mater, and arachnoid. The surrounding brain tissue was very much softened, but the tumor itself was well defined. It was of an opaque whitish color and mottled with some grey-looking substance. On microscopical examination by the curator of the museum, the cells of the grey portions were so small that they presented the appearance of nuclei. There was also in this substance a network of fibres inclosing cells in vast numbers. The tissue was freely vascularized. The white portion presented the cells in an advanced state of fatty degeneration.

The interest of the case centred in the long existence of such a disease without symptoms, and also to the fact that the hemiplegia was on the same side as the brain lesion.

Dr. Noyes remarked that the sudden blindness of the patient was evidently due to the softening of corpora quadrigemina.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 3, 1867.

Dr. A. C. Post, President, in the Chair.

EPIDEMIC CONTAGION.

Dr. Wm. C. Roberts read a paper upon the above subject, embodying the following propositions and inferences :—

Seven great epidemics are generally recognised, viz.: typhus, small-pox, scarlatina, measles, hooping-cough, influenza, and cholera, each of which is caused by a separate and specific morbid poison. To this list may perhaps be added plague, erysipelas, puerperal fever, and mumps (parotitis). Plague is never seen among us. Erysipelas and puerperal fever, with typhus, seem to be interconvertible, and *may* be one and the same disease, and derivable from the same animal poison. Intermittents are never epidemic nor zymotic, neither is yellow fever epidemic, but its virus is transportable, and its contagiousness not wholly undoubted.

Various hypotheses as to the nature of these poisons exist; atmospheric, telluric, animalcular (the most probable), fungoid, spontaneous, gaseous, solid, etc., but nothing is as yet positively known on the subject.—(See Holland, *Notes and Ref.*)

All epidemic poisons seem to have reached Europe from the East, and to have found their way hither. None have originated here; but of the manner in which they originated, nothing is known; all are of great antiquity. The poison of cholera had existed in India for centuries before it was introduced into Europe, and then into America, and is now endemic there.

These poisons, however originating, infected the human body with a specific disease, which has never changed or lost its power or property. Many of them possessed the power of re-multiplying themselves in the body, by an intra-corporeal zuma, or zymotic (ferment); the germs so multiplied being exhaled from the body with secretions, and diffused in the surrounding atmosphere, there again undergoing an extra-corporeal, intra-aerial zymosis and re-production, and infecting those brought into indirect contact with the patient, through the medium of the (impure) atmosphere. Contagion of the second genus (J. M. Smith). That germs, further multiplied and diffused through the air (intra-aerial zymosis), wafted by the wind, or advancing by their own peculiar powers of progression, invade various localities at intervals, or in succession, and produce endemics, or epidemics, which are a succession of endemics, each poison producing its own specific disease, with its attending phenomena.

Emanating thus from the bodies of the sick, they become *animal* poisons—*idio-miasmata*. Those poisons which are *animal*, specific and zymotic, are both contagious and epidemic; no others are, or become such. To say that a poison is an animal one, is tantamount to this. Diseases of malarious origin: Koino-miasmic are never extra-corporeally zymotic, never contagious in any degree, unless mixed (idio-koino miasmic), and never epidemic. Nor are the poisons transportable by air or other fomites, unless we say that that of yellow fever is, and allow it a measure of contagiousness, for which some have contended.

Such diseases arise locally from certain causes, prevail locally, and do not extend far (endemic), and cease on the cessation of their cause, leaving behind no latent germs of infection for future development. Bilious remittent and intermittent fever belong to this catagory. Influenza, the genesis of which is unknown, is per-aerially portable. Specific poisons communicate their own action and effect, analogous transformations in the bodies of the sick, and the disease produced by them is always one and the same specific, and *sui generis*. In the case of typhus, erysipelas, and puerperal fever, there is observed a curious interconvertibility of poisons, the one sometimes transmitting the other, which has caused them to be regarded as identical poisons and diseases, although each is often seen unmixed and pure. Sometimes they concur, and only one poison is transmitted, either according to its greater prominence, or under circumstances and influences un-

known. Other morbid poisons concur in the same individuals, and thus we see, that while the general rule holds good, that specific poisons produce specific diseases, poisons may co-exist, if they do not blend; and a mixed, mongrel compound, or spurious disease exist, or result, not easily to be classified, of which certain forms of typho-bilious, icteroid, or malarial fevers are examples. The poison of one disease seems superadded to the other.

Mr. Farr, Reg. Gen. of England, tells us that "zymotic" is now substituted, to avoid a tedious periphrasis for "epidemic." All epidemic (zymotic) diseases, I believe, are contagious, except influenza (which may not be zymotic), extra-corporeally, although interaerially it must be, to account for its excessively rapid development. So that, with this exception, all *epidemics*, cholera included, are zymotic and contagious; and, because zymotic and contagious, epidemic, which others, not such, are not.

Contagions of the first genus (actual contact), are intra-corporeally zymotic in a degree, producing disease only in the body of the recipient, but, by infecting his fluids (blood, lymph, pus, etc.), enabling them to communicate the same diseases by actual contact (inoculation.) They are not communicable through an atmospheric medium, nor are they mixed; for although, if blood be drawn with the vaccine virus from a syphilized child, syphilis may be communicated, yet pure fresh lymph alone communicates no such disease. The exanthemata concur; but each eruption is distinct and separate; and the rash of typhus, the rose-colored lenticular spots of typhoid fever, and patches of erysipelas, may all concur or co-exist in the same individual. Hence it seems difficult to consider them identical poisons. Two at least of the exanthemata are inoculable also.

Typhus and typhoid poisons may concur in the same individual. These are the cases which have caused the doubts as to the separate identity of the diseases, and produce in the same case a coincidence of the symptoms and pathological lesions of each. Mixture of idio and koino-miasma produces a hybrid class of fevers, of bilious or icteroid character, with yellowness of skin, and black vomit, which, as a general rule, is not seen in typhus fever. The typho-malarial fever, described by Dr. Woodward, U.S.A., in camp fevers (which he deems non-contagious); the compound Banker street fever of 1820; the Irish icteroid typhus, or yellow fever, as described by Graves in his clinical lectures; the Bulam fever of Africa, and the disease on board H. M. S. Eclair, etc., seem all of this character: and it is very difficult to make the diagnosis between them and yellow fever. A strong infusion of the *koinic* element gives to them their bilious character. A similarly predominant idio-miasm determines their typhoid character, and imparts to them a qualified contagiousness. Perhaps it is to the super-addition of idio-miasma (typhus poison), from without, or inwardly generated in course, that the typhoid character of many diseases so characterized is to be attributed.

A certain amount of intra-corporeal zymosis is necessary, in all cases, to produce disease; but, unless the morbid product so formed be eliminated (extra-corp. zymosis), no contagion follows, and the disease remains confined to the body of the recipient of the poison, and not extending beyond him. *If animal*, it may be reproduced in another by inoculation with his fluids, and becomes a contagion. If not, it dies in the patient, and is not reproduced, and hence is never contagious or epidemic (*ex. gr.* intermittent fever poison); only certain kinds of persons seem to be susceptible of this elimination of reproducible germs, this that I have called extra-corporeal zymosis, and these are the contagions proper. No disease is contagious in which this does not occur; and I think, that, unless there were a further intra-aerial zymosis, regeneration, remultiplication, and diffusion *per auram*, of specific germs, wafted by currents, or progressing by means of vehicles, *or* by a peculiar power of self-progression, whereby the poison is rapidly diffused and regenerated, and everywhere carried so that all are subjected to its effects, according to their degree of predisposition and susceptibility, epidemics could not occur.

If the poison generated in and exhaled from the bodies of the sick extended no further than a few feet from the bodies of the sick, and was there diluted, or destroyed by ventilation, I don't see how diseases could spread as they do, and become universal. Upon this point there is some difference of opinion. On the one hand, it is said that the miasms of small-pox and typhus extend only a few feet from the bedside: that "there are no grounds for the popular opinion that typhus may be propagated through the atmosphere, from a poor-hospital to the houses in the neighborhood" (Murch.), which, although opposed to the idea of intra-aerial zymosis and progression, may be true in the absence of any epidemic prevalence of the disease.

On the other hand, it is said that although the spread of the typhus virus is limited, that of small-pox does extend through all parts of the house, from a single bed, even from one house to another in the same vicinity (Wood. Pract. of Med.). It is known that more than fifty persons contracted small-pox from the body of Louis XV. by simply traversing the vast apartments of the Palace of Versailles, in which he lay mortally ill of a most virulent form of that disorder, without ever approaching his person. That the virus of small-pox has crossed a river 1,500 feet wide, and infected persons on the other side; that the poisons of scarlatina and puerperal fever infect all parts of a house or hospital for long after the removal of the inmates and thorough purification; that during a prevailing measles or scarlatina or cholera epidemic, and even yellow fever, persons are infected by walking the streets, and in houses, without approach to the sick, which is a thing of daily observation and occurrence in private families, and could not happen unless there were a poison in the air. Court-houses have been infected throughout by the entrance and transport of miasm from filthy, not diseased, prisoners (Black assizes). Murchison says that "typhus prevails, for the most part, in great and widespread epidemics, independently of smaller endemics;" and Graves distinctly says that "typhus will spread among hospital patients in the same ward, independently of anything connected with filth or foul air," not always communicated, I should suppose, by the persons of the attendants. We know that these poisons exist in the air, attack persons on ship-board, long and far away from land, persons in solitary confinement (small-pox and cholera). In cholera, hundreds of cases occur within the same day, at such distances, and in such diverse parts of a city, that they cannot have arisen from personal intercourse, or from its infection. Influenza, yellow fever, and other malaria are felt, on approaching a coast where they prevail, at some distance; and the former affects almost the entire population of a city, town, or neighborhood, in a few days, and spreads at times over an entire country or continent; its cause being certainly portable. How shall we explain these discrepancies of opinion, or account for the rapid and wide spread of these epidemics? By uniform personal contact? By fomitic infection? By *de novo* genesis, or development under meteorations or epidemic influences, which cannot apply to imported poisons, how-

ever much they may favor it, and is not known to be true of any? Or by each and all of these causes combined, together with an intra-aerial development and remultiplication of infectious germs (zymoses) and a peculiar method of progression of germs, a zymosis, not in the body alone, but in the air and soil; "the poisonous air becoming a ferment which produces its like," (Clark's Lectures, MEDICAL RECORD, lect. 3d). It is not necessary, it is not possible, in any prevailing epidemic, to look for personal contagion in every case as a cause of infection. The disease is too general, and its spread too rapid. The atmosphere contains the poison, however introduced or developed. If the disease is specific, the poison is specific, or the disease could not be induced. If it is intra-corporeally zymotic, reproducible, that is, from the bodies of the sick, it is contagious, and the infection, *in any way*, by a specific and zymotic person, is contagious; and except in the case of influenza, I don't believe that any existing epidemic is wanting in this character; and, if all poisons are absorbed, communication of specific disease, in any way, from one person to another, is contagion, whether by swallowing of air or infected fluids, or by contagious or pulmonary absorption, which is most probable. The mode of infection is the same in all, no matter where the poison is derived from, breath or skin or stools, and they are all similarly contagious (contracted, that is, in the same way), but not equally so, which depends upon the virulence and dose of the poison, and the degree of susceptibility of the exposed.

To originate epidemics, a contagious principle and a meteoratious influence may both be needed. Spontaneous development does not oppose contagion. All known contagions of epidemic character so originated, and they may again do so. But most of them are now domiciliated and domesticated, and arise now from development of small stocks of concealed contagion, which is always possible when spontaneous development is suspected. Some—yellow-fever, cholera, and influenza—are never known to originate *here;* always they are imported poisons, and their germs, if not contagious, are at least portable. No specific poison can be introduced anywhere whose germs are not portable and specific, nor regenerated, unless zymotic, intra-aerially at least; so that portability of such germs may almost be said to be synonymous with contagion. The germs of typhus, small-pox, hooping-cough, scarlatina, and cholera, are portable by fomites, perhaps those of typhoid fever, and they are all contagions. Those of yellow-fever and influenza are transportable through the air, regenerable in it, multiplicable in it, and zymotic in it, and infect by absorption. But if they be not intra-corporeally zymotic and exhalable poisons, they are not contagious. Thus intra-corporeal zymosis is the test of contagious epidemicity. No such property attends the miasms of bilious remittent and intermittent fever, which are never either epidemic or contagious. Direct contagions of the first germs differ from those of the second (indirect) mainly in that there is no extra-corporeal emanation of contagious germs. The exanthemata, although supposed to be usually of spontaneous origin (Smith, Barker, etc.), and certainly at times imported (small-pox, especially), now generally arise from rekindlement of small stocks of dormant virus always on hand in large cities, and perhaps elsewhere. Typhoid fever is supposed to be engendered by fæcal fermentation, filth, etc.; and many attribute typhus to similar local causes. Erysipelas would seem, also, to arise independently of contagion. These are not, like cholera and influenza, imported, and may have new and local organs. But it may be that no zymotic poison, once existent, ever does become wholly extinct; the exanthemata never have, and cholera is still endemic in India, and local circumstances and meteoratious influences easily and soon rekindle them. Doubtless, they occur comparatively less frequently under the improved state of hygienic science.

But I doubt if we are authorized to deny, as some zealous sanitarians have done, that there is any such thing as contagion, and assert that *all* so-called "contagions" result, in every instance, from neglect of sanitary precautions. Diseases, so originating even, would not the less *be* contagious, say small-pox, for example. How, then, deny its existence?

There is no such thing as contingent contagion: it is only qualified. Epidemic diseases are not identical; but are all analogous in general law and action, although differing specifically, yet so much alike in these, that what is true of one is true, for the most part, of all. Influenza seems to be the only epidemic poison in which zymosis (and that not extra-corporeal) is separable from contagion. No morbid poisons originate within the body; they are all received from the air into it. Those which are subsequently reproduced in and eliminated from it and become animal, whether originating in an idio or koino-miasm, are zymotic contagions. It is curious how different are the varieties and effects of poisons, whose (original) causes appear so similar. Epidemic influence alone will not account for them, and, if it did, nothing is known of its mode of action.

That *typhus* originates from ochletic miasm, is generally believed; but not by Watson, nor by Wood, that offensive effluvia, filth, and poverty produce this specific form of fever. But there is between them, whether as cause or effect, a connexion so close that it cannot be safely disregarded.

Barker attributes to the foul effluvia of drains, cesspools, etc., cases of typhus, and scarlatina even; and Murchison thinks that typhus fever may be so induced. The real character of the diseases, if any, so produced, is an interesting subject of physiological inquiry.

These statements, in regard to epidemic contagion, are generally known, and to be found in most treatises on practical medicine, and the influences from them, right or wrong, are easily drawn. But I do not know where, elsewhere, they are as succinctly collected and enunciated.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

CONVERSATIONAL MEETING, MARCH 20, 1867.

DR. ANDREW NEBINGER, PRESIDENT, in the Chair.

ANGULAR CURVATURE OF THE SPINE.

(Concluded from page 94.)

DR. BENJAMIN LEE, Philadelphia, presented to the Society a copy of his recently published papers on Pott's Disease, entitled "*Contributions to the Pathology, Diagnosis, and Treatment of Angular Curvature of the Spine.*" DR. LEE stated that the points which he desired to establish in this series of articles were threefold:—*First:* The existence of a symptom of this very distressing affection, which could be relied on almost unfailingly, and was present long before—months, even an entire year, it might be—before deformity made its appearance; a symptom therefore of the first importance, as it enabled us to commence our treatment of the disease in its most tractable stage, and before it had materially destroyed the normal curves of the spine. This symptom was a spasmodic pain in the abdominal region, sufficiently well designated by the term *gastralgia*, although it was not confined to the stomach. A case had occurred since the last meeting of the Society which so

admirably illustrated this subject, that he might be excused for briefly alluding to it.

A child, four years of age, was placed under his care by Dr. Corson, of Norristown, Pa., presenting the following history: Rather more than twelve months ago, having previously been in perfect health, on being lifted by his mother one morning, taking him under the arms in the usual manner, he suddenly shrieked out with pain, and on being asked where he was hurt, he put his hand on the abdomen. From that day forward he was subject to constant similar attacks, generally produced at first by some sudden or forcible movement of the body, and often causing him to bend double as if with cramps of the abdominal muscles. He gradually emaciated, and soon began to give evidence of difficult locomotion, the right leg especially being affected. Dr. Corson having directed the attention of the mother to the spine as the possible seat of the trouble, it was closely watched, and not until the Sunday before he was brought to Dr. Lee did the deformity show itself. At this time he was having the attacks of gastralgia regularly every evening. The protuberance was in the lumbar region. *Secondly:* The fact, which he firmly believed, that the disease in question, although often accompanying the strumous cachexy, was not, as the text-books teach, essentially tubercular in its origin. And *Thirdly:* That the most rational and successful method of treatment was the employment of force in the antero-posterior direction, for the accomplishment of which the splint of Dr. Taylor, of New York, was the means best adapted.

Dr. Hartshorne said that he had read the work just presented with much interest. He considered the symptom dwelt upon by Dr. Lee as of very great importance, but was at a loss to know how it was to be distinguished from the pain accompanying ulcer of the stomach, in the earlier stages of the latter affection, before hæmatemesis had commenced. He would be much obliged to Dr. Lee if he would indicate the signs on which he relied to make this distinction. He thought it the more difficult, inasmuch as Dr. Lee had stated that the spinal gastralgia was sometimes produced by taking food into the stomach.

Dr. Lee remarked in reply, that while it was true that the abdominal pains accompanying spinal inflammation might be caused by the prehension of food, it was so only in rare cases. The presence of blood in the matters vomited, referred to by Dr. Hartshorne, would in such cases very soon decide the doubt, if any existed. But there were other points of distinction. The spinal pain was usually spasmodic in its character, causing the patient to shriek out suddenly, and often as suddenly ceasing. It was very often traceable to movements of the body, even in cases where it might also be caused by eating. It was rarely accompanied by vomiting. But probably the most trustworthy symptom was a stiffness of the lower extremities on first rising in the morning. This morning rigidity and difficulty of locomotion were generally present as soon as there was enough inflammatory action to produce the ventral pains, and the association of the two might be considered as convincing evidence of its existence.

Reciprocation of Medical Services. — Professors Dumreicher and Langenbeck, the former Austrian, the latter Prussian Surgeon-General, have entered into an unpleasant discussion as to whether the Prussian medical officers did or did not neglect the Austrian wounded after the battles in Bohemia. It is a matter of veracity, or perhaps the shield was looked at from different sides.

Correspondence.

ABORTION IN THE CHURCH.

To the Editor of the Medical Record.

Dear Sir—I was quite interested in the account given in your recent issues of the stand taken by one or two church journals against the crime of abortion. Every medical man, and every Christian, has reason to rejoice that the initiative has thus been taken, and that there is a chance of placing the enormity of this dreadful crime properly before the eyes of the clergy, as well as the members of their flocks. I do not wish to cast any reflection upon the character of true ministers of the gospel, for such should always be above suspicion, but there are some who unworthily assume the titles and responsibilities belonging to that profession, and who not only wink at the practice but who urge its committal upon their own wives.

Permit me, sir, to cite a case in point: A few weeks ago a well known clergyman in the district in which I reside called at my office for a confidential professional int rview, and in the course of our conversation he came at the subject, which was that of a proposal for aid in producing an abortion upon his wife. After I had sufficiently recovered my surprise at this demand, I expostulated with him and tried to use the usual arguments against the commission of the act, but, strange to say, while admitting the truth of my assertions, as he termed it, "on high moral grounds," he declared it to be his intention to have it done by some willing party upon whom he intended to call. It was a matter of expediency to him, he being, as he said, so peculiarly situated that a birth at the time it would be due would be the most inconvenient thing in the world. He was not loath to have a family, and he pretended to believe that the Almighty could protect his wife through the parturient act, and made quite a number of pretty little arguments in favor of his project. But what was his excuse? Simply this—He was to sail shortly as a missionary, and he did not wish to *have his wife confined on shipboard!*

I have no doubt that other medical men have similar experiences, but for myself I must confess that this was rather a startling one, as proving the deep root which this crime has taken among that class of individuals who should know and do better. It is this class particularly that may be benefited by the discussion of the subject in religious papers. This man has probably ere this been served, but I hope, if such be the case, that he will repent of his sin on the voyage, and make himself a fit teacher for the poor heathen.

Yours etc., H.

New York, May, 1867.

Responsibility of the Chinese Physician.—The physician is greatly responsible for his patients. If he fails to cure, the patient or his friend may prosecute him at once. If through any inattention or mistake he has caused the death of a person, he must pay the penalty—which penalty generally means the support of the family. If through a fatal medical blunder this happens—he is for ever afterwards prohibited from practising his profession—a regulation that might, perhaps, prove advantageous in other countries. Visits are never charged; they simply charge for the medicine used, and it is always on trust until the patient gets better—conditions not very favorable for large incomes and great wealth. —Dr. Wiley, *Cinn. Lancet and Observer.*

Obituary.

PROF. J. M. ALLEN.

DIED APRIL 7, AT LOWELL, MASS.

Dr. Allen was born in Princeton, Mass., in the year 1815, and, in early life, enjoyed only the advantages of a common school education in that quiet agricultural town. He entered Yale College in 1834. In 1838, he went to Philadelphia to prosecute medical studies and attend lectures. In 1840, he graduated at the University of Pennsylvania, and immediately became a teacher and lecturer on anatomy connected with a private institution. Afterwards he occupied for several years the place of Demonstrator of Anatomy in the Jefferson Medical College, and from there he passed to the Professorship of Anatomy and Physiology in the Pennsylvania Medical College, which post he held seven or eight years.

During this time he prepared and published the *American Medical Dissector*, a work which possesses great merit and is used as a text-book by medical students throughout the country. Close and continued application to professional duties as well as to scientific and literary pursuits, broke down his health and compelled him to suspend his labors. At this time he had a severe and lingering fit of sickness, from which his constitution never fully recovered. Some six or seven years ago he came to New England to visit his friends and recruit his health, making Lowell mainly his home. On account of his feeble state of health, he avoided all public labors and medical practice, except what incidentally came into his hands, and most of this was a gratuitous service for the poor, for whom his sympathies were always warmly enlisted, and by none (except his family and relatives) will he be so much missed or so long remembered as by this class. Here he was but little known, except to a few individuals and families who casually made his acquaintance or sought his professional advice. Being himself an invalid, he sought a quiet and retired course of life. On April 1, he was attacked with pneumonia, which, with organic disease of the heart, in a constitution already enfeebled, afforded a very small chance of recovery. He was confined to his room only three days, when death released him from his sufferings.

Medical News and Items.

PERSONAL.

Dr. Edwin Powell, of Chicago, has been promoted by the President to the rank of Colonel by brevet. The commission dates from the 13th of March, 1865, and was given "for faithful and meritorious services during the war."

CIRCULAR ORDERS, ETC., FROM SURGEON-GENERAL'S OFFICE.

Washington, D. C., *January*, 28, 1867: Circular Orders No. 1.—It is known that during the War of the Rebellion there were instances of primary amputation at the hip-joint for gunshot injury, performed at field hospitals, and not made the subjects of special reports to this office. With much difficulty the details of several such cases have been collected. It is believed that others may remain unrecorded. In order that the data of the office in relation to this operation may be as complete as possible, you are respectfully requested to report any facts, however slight, within your knowledge, in reference to cases of amputation at the hip-joint in the military surgery of the War of the Rebellion, bearing upon cases other than those enumerated at page 50 of Circular No. 6, Surgeon-General's Office, 1865.

By order of the Surgeon-General.

C. H. Crane,
Assistant Surgeon-General, U. S. A.

Washington, D. C., *April* 4, 1867: Circular No. 2.—Medical officers, and others interested in the progress of medical science, are invited to forward contributions to the Army Medical Museum, which is now prepared for their reception.

Besides interesting medical and surgical specimens, which will be forwarded as heretofore, the following classes of articles will be collected and forwarded by those medical officers who have opportunities for so doing.

1. Rare pathological specimens from animals, including monstrosities.
2. Typical crania of Indian tribes, specimens of their arms, dress, implements, rare articles of their diet, medicines, etc.
3. Specimens of poisonous insects and reptiles, and of their effects on animals.

Attention is called to Circular Order, No. 3, dated Surgeon-General's Office, April 3, 1867, a copy of which is herewith forwarded.

J. K. Barnes,
Surgeon-General, U. S. A.

War Department: Washington, D. C., *April* 3, 1687, Circular No. 3.—The following Order from the Acting Quartermaster-General, U. S. Army, is respectfully furnished for information of Medical Officers, U. S. Army:

Washington, D. C., *March* 25, 1867: Quartermaster-General's Office, General Orders No. 27.—Officers of the Quartermaster's Department, in charge of Government trains returning from frontier or other remote points, are authorized, upon the requisition of Medical Officers, to furnish transportation by such trains for collections of specimens for the Army Medical Museum, when such transportation can be furnished without injury to the public service.

D. H. Bucker,
Acting Quartermaster-Gen., Brev. Maj.-Gen. U. S. A.

By Order of the Surgeon-General.

C. H. Crane,
Assistant Surgeon-General, U. S. A.

Washington, D. C., *April* 20, 1866.—No. 4.—In view of the possible prevalence of Cholera during the approaching summer the following instructions are promulgated.

Every endeavor will be made by medical officers to prevent the introduction of Cholera from infected commands, or its conveyance from point to point, by a "quarantine of observation" upon all detachments of recruits or troops, arriving or departing from depots, posts, or recruiting stations, at or near which this disease prevails; prompt reports of its appearance in commands, either *en route* or in garrison; and isolation of all cases as far as practicable. In addition to the strictest hygienic police, enforcement of personal cleanliness, and thorough disinfection, attention should be paid to the quality of the water used for drinking and cooking purposes. When pure rain water cannot be procured in sufficient quantities, and the spring or river water contains organic impurities, it should be purified by distil-

lation, or the noxious matter precipitated by permanganate of potash. From half a grain to one grain of the crystallized permanganate (or its equivalent in solution), added to one gallon of water, should produce a decided pinkish hue, which disappears within twenty-four hours (if the salt has not been used in excess); the water should then be drawn off, and it is ready for use. Turbid water, such as that of the Rio Grande, Lower Mississippi, and its tributaries, should be filtered, or allowed to settle, before using. The deposit of impurities can be hastened by the addition of powdered alum in small quantities well diffused by stirring. It is always, but more especially in times of threatened danger of pestilence, the duty and privilege of medical officers to submit the practical suggestions of experience and professional knowledge for the protection of the health of troops, to their commanding officers; and the history of the epidemic of Cholera in 1866, shows that only by combined and untiring vigilance, energetic action, and rigid enforcement of hygienic measures, within reach of every commander, can we hope to avoid, keep in check, or eradicate this disease.

Besides the usual reports of sick and wounded, every medical officer in charge of Cholera cases will forward to the Surgeon-General's office, at the close of each month, a list of Cholera patients in the following form:

Special Report of Cholera Patients at . . . . . .

Month of . . . . . 186 . .

Name.	Nativity.	Age.	Rank.	Regiment.	Company.	Length of service in mo's.	Date of attack.	Date of recovery.	Date of death.	Remarks.

. . . . . Surgeon, U. S. A.

Successful methods of treatment and results of autopsies will also be communicated.

The senior medical officer at every post at which Cholera appears, will make a special report to the Surgeon-General setting forth any facts he may be able to ascertain as to the introduction of the disease, and especially those bearing upon its importation from infected points by recruits or others, or its apparently spontaneous origin at the post.

J. K. BARNES,
Surgeon-General, U. S. A.

PROPOSED REPEAL OF MAINE LIQUOR LAW.—The Maine or Prohibitory Law was called up in the Connecticut House of Representatives, on Thursday, and after much warm discussion, a resolution was passed instructing the proper committee to inquire into the expediency of its repeal, and the enactment of a license law.

VIS MEDICATRIX NATURÆ.—A correspondent of the Richmond *Dispatch* has seen in Fluvanna County, Va., a lady, 97 years of age, who, until quite recently, never was sick, and never took a dose of medicine in all her life. She enjoys even now the full use of all her mental and bodily powers.

MORTALITY AMONG THE SHEEP IN MICHIGAN.—Great mortality, owing to a low grade of fever and diarrhœa, is said to be prevailing in Michigan. The pathology of the disease has not been ascertained.

HOME FOR LITTLE WANDERERS.—The foundation stone of the new Home for Little Wanderers, organized by the Howard Mission, has been laid in the Bowery on the site selected. The house is to be eighty feet long and fifty deep, and will be large enough to accommodate seven hundred children, and will also contain a hospital for sick children, a day nursery, where mothers can leave their infants while at work out, besides having spare lodgings for homeless girls.

THE POPULATION OF LONDON, i. e. the whole area included in the circle of fifteen miles radius from Charing Cross, is estimated at 3,521,267 souls; 107,992 births and 80,129 deaths were registered in London last year, both numbers being above the average record, and the excess of births over deaths much less than the previous year. The mortality was at the rate of 26.5 per 1,000, which is two above the average of the last twenty-seven years.—*Medical Times and Gazette.*

THE SPRINGFIELD SOCIETY FOR MEDICAL IMPROVEMENT.—The *Boston Medical and Surgical Journal* calls our attention to an error in locating the above society in Illinois instead of Massachusetts. For this the journal in question has our thanks. When, however, it charges us with copying the item in regard to the Society from their columns, it is in error. The item was sent to us direct from one of the members of the Society who desired its insertion, and as no State was mentioned we had to guess at it. The idea of inserting "Illinois" to cheat the "enterprising and industrious friends" in Springfield of "the credit of their professional zeal" in the matter is simply preposterous. Our readers will please bear in mind that the Springfield Society for Medical Improvement is located in *Massachusetts.*

THE LYING-IN ASYLUM.—The forty-fourth anniversary of the Asylum was recently held, Mrs. Thomas Addis Emmett presiding. The proceedings were opened with prayer by Rev. Dr. Burchard, who afterwards made a forcible address. He spoke of the benefits conferred by the institution, and said that unfortunately the number of those who had actively supported it was yearly becoming less. The city could not, he said, afford to lose such an institution, and he urged those present to use their influence in securing an increased interest in the Asylum.

The Annual Report was then read, from which it appears that the total receipts of the institution during the year were $4,616 64, and the expenditures $3,900 34, leaving a balance of $716 30.

The Report of the Resident Physician, Dr. Sterling, shows the following facts: Number of confinements in the house, 104; children born, 104—males, 59; females, 45; stillborn, 4; the number of women who left the Asylum after their confinement in good health was 102; number remaining to be confined, 5; number of cases attended by district physicians, 269; total number, 379; whole number confined in the Asylum since its foundation, 3,332; attended by district physicians, 11,827; total, 15,159.

Addresses were made by Drs. J. P. Garrish and J. R. Wood, who spoke in eulogistic terms of the management of the Asylum, and the remarkably successful treatment of patients, after which the meeting adjourned.

SENSIBLE ADVICE.—We recently saw, upon a fence in the interior of this State, the advertisement: *Use Dr. H——'s antibilious Pills*, under which some irreverent wag had written, "*and prepare to meet thy God.*"

GERMAN HOSPITAL FUND.—The Ladies' Aid Society have recently donated $3,000 to the fund.

CHOLERA.—A case of Asiatic Cholera has been reported at St. Catharine's, Canada.

Original Communications.

CASE OF ABSCESS IN THE APPENDIX VERMIFORMIS CÆCI.

PROF. WILLARD PARKER'S OPERATION BY INCISION—RECOVERY.

By J. H. HOBART BURGE, M.D.,

SURGEON TO LONG ISLAND COLLEGE HOSPITAL, ETC.

Miss K. S——, aged 15 years, attended a party on Monday evening, March 4, 1867, and, although not feeling well, ate chocolate ice-cream. The next morning she was attacked with pain in the bowels, had two alvine evacuations, and vomited freely. The pain continuing, her mother gave her repeated doses of a morphine mixture which I had prescribed several months ago for an attack of colic in the same patient. The pain was not relieved, and I was called in the evening. She was of nervous temperament and exceedingly sensitive. I found her with knees drawn up, and abdomen so tender, that she made the muscles as tense as possible to resist any pressure that might be attempted. She referred the pain to the umbilical region. I ordered tr. opii camph. 3 i., to be repeated, if necessary, from time to time through the night. The first dose relieved sufficiently to produce sleep, yet upon waking the pain was renewed.

March 6th.—No relief; general tenderness of the abdomen, but most sensitiveness in right inguinal region. Prescribed mixture containing chloroform gtt. v. to each dose, repeat every two hours. Evening visit—patient has slept some; but still complaining. Fearing there might yet be some irritating matter in the bowels, I ordered an enema of hop-tea Oss., ol. ricini ℥ i. and tr. opii gtt. xx.

March 7th.—The injection was retained. Patient has slept some. Pulse, from commencement of attack, has been pretty uniformly 120. Repeat the injection without the laudanum, continue the chloroform mixture, and give tr. opii camph. 3 j. if there is any increase of pain. Bowels moved moderately.

8th.—Paregoric has been given but twice; relief partial; pain and tenderness more marked in right iliac fossa.

14th—Bowels have been moved every day moderately, since last record, and yesterday three times. Pain and tenderness partially controlled by tr. opii camph. 3 i. morning and evening, and at times aquæ camph. 3 i. every hour. Has, to-day, slight chills; pulse 130; tongue white and moist; skin slightly dry.

17th.—Bowels moved every day; pain and tenderness less. One teaspoonful of paregoric morning and evening has been sufficient to procure sleep; pulse has fallen to 90; skin and tongue moist. There is a firm mass in the right inguinal region, which is tender on pressure. Concluding that I had one of but two things to deal with—either a scybalous mass, still retained in the cæcum, or an abscess in the appendix—I gave hydrargyri submuriatis gr. vj., which caused a free evacuation, but made no impression on the mass. The tumor was not large, and no fluctuation could be detected.

18th.—Announced to the family the serious nature of the case, and called Prof. Willard Parker, who, upon hearing its history and examining the patient, advised an immediate incision. At my request he operated, while I administered chloroform. An incision was made, three inches in length, directly over the tumor, its central portion extending through the muscles and the fasciæ transversales. An exploring needle was thrust into the tumor, and at first there seemed to threaten a pretty copious hæmorrhage. It proved, however, to be mainly serum, and pus immediately followed. The wound was enlarged, a piece of lint introduced, and slippery elm poultice applied. After consciousness returned, sol. morph. (Magendie's) gtt. x. was given. Patient slept quietly for more than two-thirds of the time for the next thirty-six hours, generally two or three hours at a time. Has not cared for food since first attacked. Takes a little milk-punch, toast, and crackers.

22d.—Pulse, since operation, very uniformly 100; to-day, 112. Skin and tongue moist; no pain, no thirst. Has taken no medicine since the day of the operation. Abscess continues to discharge moderately, and incision looks healthy.

23d, 24th, 25th.—Morning, pulse 92; evening, 112. Appetite slightly improving.

26th.—Some uneasiness in stomach and bowels; at times amounting to pain. There is not and has not been any tympanitis; pulse a little hard. Patient did not rest as well last night; aqnæ camph. 3 i. every hour.

27th.—Had a small, natural passage last night; still feels uncomfortable in stomach and bowels. Ordered in the evening, an enema of warm water Oj., and fine salts 3 j. The patient resisted it so strongly that the nurse failed to give it.

28th.—Rested well, and is very comfortable to-day.

29th.—Pulse 88; discharge from abscess laudable pus only.

31st.—Pulse 80; had a small, natural alvine evacuation last night; wound granulating finely.

April 10th.—Bowels quite regular; wound nearly healed; appetite good; patient gaining strength rapidly.

THE MEDICAL USE OF ELECTRICITY.

By G. M. BEARD, M.D., AND A. D. ROCKWELL, M.D.

OF NEW YORK.

No. V.

PROLAPSUS UTERI.

Dr. Seiler, of Paris, published a work in 1860, entitled "*Galvanization par Influence*," in which he reported a number of cases of uterine displacement that had been relieved or cured by electricity.

In prolapsus uteri general electrization is very often of great service, chiefly by its tonic effects on the system at large, and on the walls of the vagina. All gynecologists will agree that prolapsus uteri is usually associated with relaxation of the vaginal walls, and also with general debility, and that whatever will give tone to the system and to the weakened parts must be of service.

Miss T——, an unmarried lady, aged 30, applied for treatment for falling of the womb of the second degree, from which she had suffered for nearly six months. Previous to the first symptoms of prolapsus, persistent leucorrhœa had annoyed her for some time, and had continued up to the day she came to us. She complained also of some menorrhagia, and this, together with the constant leucorrhœa, had deprived the vagina of its tone. These conditions, however, were evidently associated with no actual uterine disease; but her general health was quite feeble. If it were a case for electricity at all, it was plain that she needed its tonic influence. We commenced, therefore, with mild, general applications, increasing the strength of the current at each visit, as she was able to bear. At each sitting, also, the electrode was pressed for a few minutes against the os and the walls of the vagina. The beneficial

results of this course of treatment were soon observable. Her appetite, which had been capricious, became more rational, and her strength increased with marked rapidity. The vaginal walls seemed to gain tone day by day, until after the sixth application the uterus was restored to its normal position.

We shall merely allude to the other indications for the use of electricity, for if the general principle in regard to its tonic and corrective effects be true, then it is evident that it may be fairly tested as an adjuvant wherever such effects are desired. It has been used in surgery in the form of *galvano-cautery*, for discussing *tumors*, for stimulating *ulcers*, for hydrocele and chronic urethritis. It has also been used in *intermittent fever*, and with good results. In *incontinence of urine* associated with general feebleness, it often works very effectively.

Much has been said of its powers as a *galactogogue*, and some interesting results as well as failures have been reported. In *progressive locomotor ataxia*, or Duchenne's disease, this agent has not achieved very great results. In *epilepsy* we have sometimes found it to be positively and speedily beneficial, and sometimes it appears to be entirely inoperative.

But, notwithstanding the fact that electricity, employed in the manner we have described, is indicated in a wide range of diseases, it is as yet very far from being a panacea, even in the most skilful and practised hands. For some diseases it is found to be in no way adapted by our method of application, although a wider experience may teach us *that the fault lies in the method of administration and not in the remedy*. In the treatment of shaking palsy, we have uniformly failed to give the slightest relief; and in cases of paralysis, dependent on *persistent* lesions of the nervous centres, we do not expect to be of much service. But so difficult is it, even for the ablest diagnostician, to discriminate between the different forms of paralysis, that we usually make at least a few trials on most of the cases that are brought to us, in order to ascertain, if possible, by the electric test, whether there be any chance of relief. We are oftentimes agreeably disappointed by a favorable issue in cases that at first seemed to promise but little.

We have already stated that faradaization, as we employ it, does not seem to be adapted for cases of pulmonary tuberculosis the first stage. Dr. Bastings, of Brussels, has recently published a work, in which he claims to have cured twenty-five cases of phthisis by means of the galvanic stream, applied around, not through, the chest, for the purpose of increasing the muscular development. The theory of his treatment, as we understand it, is substantially the same as that advocated by Dr. Davis, in his recent work on "Conservative Surgery." The book is prepared with apparent fairness, and we shall endeavor, as occasion offers, to subject his theories to a practical test.

But there are certain temperaments and certain stages of disease that will allow only of very mild applications of electricity, where indeed unpleasant effects seem to follow, temporarily at least, unless the treatment be commenced with great caution.

Mr. F., sent to us by Dr. Fordyce Barker, complained of a kind of neuralgia of the neck of the bladder. He was a stout, well formed man, and in all other respects was in perfect health. The first applications were made with the positive pole on the lower part of the spine, over the lower part of the abdomen, and against the perineum, mildly at first, but afterwards with greater power. For a number of days after the fourth visit the patient complained of soreness of the muscles (a not unusual temporary effect at the commencement of treatment), and of general prostration, which annoyed him for several days. Such cases, in healthy individuals, however, are purely exceptional.

For the majority of patients even an overdose is only followed by a feeling of soreness that soon passes away.

Those who receive an application of too great power will not usually experience the prostrating effects before the following day; but even to this rule there are exceptions. In very aged persons, or those enfeebled by disease, we always begin with mild applications, and gradually increase the strength according to the indications, allowing intervals of several days between the visits. It should be remarked, however, that we have obtained some of our most successful results in cases that at first seemed to be injured rather than benefited. Occasionally, in those affected with digestive derangements, the first operation causes prostration and vomiting, that seems to clear out the system, and prepare the way for recovery.

We close with a few brief suggestions for the benefit of any who may be induced to study this subject for themselves.

1st. Get the best apparatus and become thoroughly familiarized with the details of its management. Much of the discouragement that has thus far attended experiments in this department has been due to the fact that it has been impossible to obtain any convenient, easily adjusted apparatus. The old-fashioned magneto-electric machines, where the electricity is generated by turning a crank, are to the last degree inconvenient, and it is not to be wondered at that those physicians who use them soon become disgusted with the whole subject. The electro-magnetic apparatus that we employ, and which we decidedly recommend, is manufactured by Jerome Kidder, of this city. It has a powerful helix, a very readily managed armature, and is run by the ordinary Smee's Battery. A moderate amount of experience will enable one to manage it successfully, and to keep it always in order.

2d. Make the applications *general*. *Localized electrization*, according to the method of Duchenne and his followers, is serviceable in paralysis, acute neuralgia, and kindred affections; but where a general tonic effect is desired, as in dyspepsia, rheumatism, amenorrhœa, chorea, constipation, anæmia, and in other diseases associated with deficient vital energy, *general electrization* is indispensable.

The modus operandi of general electrization is as follows:—Male patients remove their stockings and all their outer and under-clothing from the upper part of the body, and place their feet on the piece of copper to which the negative pole is attached, while the operator applies the positive, either the sponge or the hand (when the current passes through his own person), down the spine and over the vital organs. Ladies remove their dress and loosen their under-garments, and throw over their shoulders a shawl, or sheet, to prevent exposure. The most thorough form of application demands that the entire surface of the body should be gone over with some regard to order.

Special pains should be taken to avoid the scapula, clavicle, sternum, crest of the ilium and tibia (or when they are touched, to carefully graduate the current), inasmuch as these and other bony prominences are very sensitive to the electric current.

3d. Be prepared for the occasional occurrence of unpleasant or equivocal symptoms at the outset of a course of treatment. The soreness of the muscles, headache, and general depression, that are sometimes experienced a day or two following the first application, will soon pass away, provided the subsequent treatment be judicious.

Applications to the head should *always* be made with the hand, and should be very mild. Cases that begin unfavorably often result in the most complete cures.

For patients who are much reduced it is best to allow intervals of several days between each application, especially at the beginning of the treatment. In the majority of cases sittings may be held every other day, or when merely localized electrization is employed, every day.

4th. Let the first tentative applications be mild and of short duration, say from five to ten minutes, and increased in strength gradually as the patient is able to bear. Afterwards, the strength of the current, whether employed with the hand or sponge, should be as great as can well be borne. Let the patient be *comfortably uncomfortable.*

5th. For nearly all chronic affections the treatment should be persistent. While great and beneficial effects are often derived from two or three applications, a complete or approximate cure can only be achieved by continuance of the treatment, varying the strength of the current and frequency of the applications according to the progress which is made. Cases of paralysis of long standing demand a protracted course of treatment, even where there is no very serious lesion of the nerve centres. In many cases of paralysis, and in some phases of rheumatism, the improvement may be hastened by the use of the continuous galvanic stream.

6th. Although general electrization is indicated in a large variety of diseases, it is very far from being a panacea. It is a *tonic*, and it is to be employed on the same principles, and subject to many of the same limitations as are all other tonics, except that it is more rapidly and surely effective than any internal medication. If the system be below par, as a result of any chronic disease, or combination of diseases, then general electrization is indicated in conjunction with or prior to the use of iron, quinine, bathing, air, exercise, society, and all other tonic influences whatsoever.

But it should ever be remembered that it is *general electrization*, employed in the manner we have described, and not "electricity" or "localized electrization," that produces constitutional tonic effects, and thus cures disease.

The result of the treatment will depend as much on the skill and perseverance of the operator as upon the powers of the agent he employs. Success in this, as in all other departments of science, is reserved for those who, unswerved by prejudice and unbiased by theory, seek only for the knowledge that comes from careful, patient, and repeated experience.

914 Broadway.

The Reason why our Teeth Decay.—The reason why the teeth of people of later days are more decayed than were those of past generations, is, that we are now further from Nature's simple plan. Indeed, the terrible condition of the present generation may be said to be one of the penalties of civilization; and the decayed condition will increase in exact ratio with the luxuriousness of the diet. Dentists should discourage the general use of pickles, lemons, and other acid substances, and bring their patients as near as possible under the influence of the hygienic law. Another great cause of disease by the production of acids, is the fermentation of food lodging in the teeth after eating. The remedy for and preventive of this is cleanliness, absolute cleanliness. The doctor recommended the use of antacids with the brush. Solution of carbonate of soda, lime-water, etc., could be advantageously used three times a day for an indefinite period.—*Dr. Cushing (Dental Register).*

EXCISION OF THE ENTIRE OS CALCIS FOR CARIES.

By F. A. BURRALL, M.D.,

SURGEON TO THE NORTHERN DISPENSARY, VISITING SURGEON TO CHARITY HOSPITAL

William Keogh, born in the United States, of Irish parents, and aged eight years, was brought for the first time to my office, Oct. 8, 1866, from Jersey City, where he lived. I was informed by his parents that nine months previously he had been in the habit of standing for a long time upon the ice, and on one occasion he became much chilled, soon after which a swelling occurred beneath the left external malleolus, over the os calcis. This was opened by the attending physician and discharged purulent matter, which discharge continued to the date of his visit at my office. The patient had been under treatment at intervals since the commencement of the disease, but as is usual in caries of the tarsal bones, the malady progressed steadily, and amputation of the foot had at last been recommended as the only means of cure.

The general health of the patient was good. Although pale, his skin was not transparent, and his appearance not that of a scrofulous child. His parents were healthy and did not admit any strumous tendency, while his six brothers and sisters enjoyed good health.

The foot was somewhat inverted, apparently owing to an adhesion over the tendons of the peronei muscles at the outer malleolus, which prevented them from contracting. The integument was red and thickened, and the vicinity of the ankle much swollen. The lower portion of the foot still retained a marked healthy appearance. Pressure over the seat of disease did not cause much pain. A moderate purulent discharge flowed from three small openings on the external surface of the foot over the os calcis, and a probe passed into these, struck upon dead bone. This discharge had often contained osseous particles. There was good ginglymoid movement in the ankle-joint, but the foot was useless for walking.

The parents being extremely anxious that the foot should be saved, a tentative treatment (partly for the purpose of reducing the size of the parts surrounding the joint) was commenced, consisting in the firm application of a roller around the joint, the openings being left uncovered and dilated with compressed sponge. The poultices which had been in use were discontinued, and the syrup of the iodide of iron was ordered to be given three times daily. Under this treatment the joint became smaller; but there was no decided improvement, so that an operation was considered necessary. Dr. Gurdon Buck, who saw the case about this time, recommended that a free incision should be made upon the outer side of the foot down to the diseased parts, and the subsequent steps of the operation be regulated by the extent of the disease.

Nov. 1, assisted by Doctors M. H. Henry, J. C. Morton, and L. Weber, the patient was etherized and a horizontal incision made, extending from the inner edge of the os calcis, severing the tendo-achillis and going down to the bone, to a point opposite the calcaneo-cuboid articulation. A vertical incision led from this point to just within the sole, freely opening the calcaneo-cuboid articulation. While making this incision the scalpel struck a sequestrum which proved to be the loosened facet of the os calcis which articulates with the cuboid. This detached fragment was rough and bare.

The flap was now dissected downwards, and the os calcis was found suppurating and disintegrated, but still firmly held by its attachments. Partly by the cutting edge of the scalpel, partly by its handle, and partly by

evulsion, the bone was removed. The surrounding surfaces were in a healthy condition, with the exception of the cuboid, the cartilage of which having been partially removed during the operation, showed considerable vascularity of that bone. The synovial membranes between the astragalus and os calcis were uninjured, as well as the posterior tibial vessels and nerve. About twenty minutes were consumed by the operation. The peronei muscles and vessels were divided, but no ligatures were required. An examination of the removed bone showed that its shape was very much altered by carious disintegration. The cavity was washed with a dilute solution of liq. sodæ chlorinatæ and the edges of the wound united by silver sutures. A plaster of paris bandage was then applied from the upper part of the leg to the toes, so arranged as to leave the wound uncovered. On the wound were placed cloths containing ice, and directions left to cut the plaster band should it be found too tight, and substitute cold water for ice, if the ice proved unpleasantly cold. The heel was also supported by a diachylon strap.

No bad symptoms followed the operation. Union took place throughout nearly the entire line of the wound. The after treatment consisted in the use of the plaster of paris splint, an injection of the cavity with a dilute solution of liq. sodæ chlorinatæ twice daily, scrupulous cleanliness in the vicinity of the wound, water dressings, to which Labarraque's solution was also added, and good nourishment. On the 13th of November, the patient was able to go down stairs, the leg being suspended by a bandage which passed around the neck, and on the 18th of December all discharge had ceased from the wound, and the patient could walk with a slight limp. At present (March 7) the boy attends school, and walks and runs in ordinary shoes without difficulty. Scarcely any limp remains, and no apparatus has been necessary. The foot has become reduced almost to the size of its fellow; the inversion has disappeared, and the heel is resuming a natural appearance, growing firm and full. The tendo-achillis has become strongly united, and the movements of the foot, with the exception of eversion, which was very limited before the operation, are performed with facility. It is no exaggeration to characterize the result as very satisfactory.

Remarks.—Different opinions have been advanced as to the comparative merits of gouging or excision in disease of the os calcis. Dr. R. M. Hodges, in his work on "The Excision of Joints," uses the following language on page 189:

"For the removal of the os calcis, a regular operation is performed. The operations of Mr. Hancock and Mr. Greenhow in June and August, 1848, are claimed to be the first instances of this. But it was practised by Monteggia, of Milan, twenty-five years before, and also by Heine in 1834. It has now been performed many times for carious disease, and with tolerable success. Of the twelve cases reported by Mr. Greenhow, ten were successful, and in two amputation was subsequently required. The os calcis has also been excised for injury: four operations in the Crimea, in the year 1855-56, having all been followed by a favorable result.

"There can hardly be a doubt, however, that gouging is preferable to excision, and better applicable to this bone than to any other of the tarsus; its use in supporting the foot, and for the implantation of the tendo-achillis, may thus be retained, as a portion of the bone and the attachment of the tendon are preserved by the former operation, but can never be by the latter."

On the other hand, Dr. T. A. Holmes, in one of a most interesting series of papers on "The Treatment of Caries of single bones of the Tarsus and Metatarsus by Excision of the Entire Bone,"* says:

"What I wish chiefly to urge in the present communication, is the great advantage to be derived, in cases where the greater part of any of the tarsal or metatarsal bones is carious, from the removal of the *whole bone*. In a previous paper "On Excision of the Hip," I have pointed out as one of the great obstacles to success in that operation, the uncertainty which must always exist as to the extent to which the softened bone usually found in the acetabulum requires removal; that is to say, how much is incurably disorganized, and how much will recover if the other diseased parts are removed. In consequence of inevitable errors on this head, we often find that the exposed sections of bone take on the same carious action as the original joint-surfaces, and the operation is partially frustrated. The same is the case in the gouging operations practised on the tarsus. But in the case of the hip we have no choice; in that of the tarsus, usually we have. When only one bone, or only two contiguous bones, are affected, it is usually easy to remove the whole organ diseased; and when this is done—that is to say, when a wound is left which contains nothing but the soft parts and the healthy articular cartilages of the contiguous bones, I have never yet seen a case in which the wound did not heal soundly, and I believe permanently; and this is, therefore, the practice which I now always adopt in cases where limited disease of the tarsus affects only one bone to a considerable extent."

In Prof. Syme's "Principles of Surgery," page 703, it is stated:

"When the *os calcis* alone is affected, the disease may be extirpated by making a crucial incision on the fibular side, and then digging out the carious part with a gouge."

Dr. Morrogh, of New Jersey, successfully removed the whole of the os calcis, and a case of excision of the entire bone in an adult was published by Dr. Carnochan in the *American Medical Gazette* of June 1, 1857, which terminated successfully.

From the above references it is seen that, although gouging is considered preferable to excision when the disease is of moderate extent, yet Dr. Holmes regards with partiality a comparatively early removal of the entire bone. In Keogh's case, excision was the only alternative, as the bone was much disorganized. Necrosis was also present, for the facet of the os calcis which articulated with the cuboid had been separated in bulk and was a detached foreign body. The operation performed was the one recommended by Dr. Holmes in the papers to which reference has been made.

It would be difficult to lay the blame of the carious action in the case upon a strumous diathesis. The parents of the child are healthy, as they informed me were also their parents; his brothers and sisters also enjoy good health, and he is a hardy-looking boy. It is easier to explain the origin of the disease in the following manner:—As a result of exposure to cold and moisture (from standing upon the ice), the vitality of the external side of the os calcis, more superficial than the inner, and with a more limited vascular and nervous supply, became unusually depressed, the balance of the circulation disturbed, and a limited inflammation followed. Then pressure of the periosteum upon the inflamed part resulted in death of a portion of the subjacent bone, and subsequent ulceration, which from its seat was disposed to be of a carious nature.

An interesting feature in this case is the local charac-

* London Lancet, Jan. 21, 1865.

ter of the disease, which, although of nine months' duration, was limited to one bone, a clean cavity having been left by its removal.

These operations are rather rare. If unsuccessful, they may be followed by amputation of the leg; if successful, the remaining foot is much better than any artificial one, and in the present, as probably in many other instances, almost as good as its fellow.

DEEP CERVICAL TUMOR,

THE REMOVAL OF WHICH INVOLVED THE EXSECTION OF A PORTION OF THE INTERNAL JUGULAR VEIN,

WITH SOME REMARKS UPON

THE LIGATION OF VEINS IN GENERAL.

By WILLIAM WARREN GREENE, M.D.,

PROFESSOR OF SURGERY IN BERKSHIRE MEDICAL COLLEGE, AND IN THE MEDICAL SCHOOL OF MAINE.

On the 6th of April, 1864, Mr. Saunders, of Cheshire, consulted me with regard to a tumor upon the left side of the neck which he first noticed three years before. It had slowly and regularly increased in size, and for three months previous had been the seat of almost constant pain, while the whole side of the neck and head had been affected with a neuralgia sufficiently severe to deprive him, in a great measure, of sleep. For the past few weeks his appetite, flesh, and strength had failed, and he was very much depressed. The growth was partially covered by the sterno-mastoid muscle anterior, to which it was quite prominent. It was regular in outline, fluctuating, but tense and somewhat tender. It was *apparently* quite movable, and seemed about the size of a croquet ball.

The patient, understanding the liabilities, having elected an operation, was etherized; and with the assistance of Drs. Smith and Paddock it was performed as follows: The shoulders being elevated upon a block of wood, the head, falling backwards a little, was turned to the right so as to render the coverings as tense as possible, and an incision made through the skin and superficial fascia, commencing just behind the angle of the jaw, and extending over the most prominent part of the tumor downwards nearly to the clavicle. The deep fascia was divided upon a director, and the cyst readily exposed. Its walls varied in thickness at different points, and were so thin at the apex as to burst under the pressure of the fingers. The opening was immediately closed with broad-bladed forceps, and there was not sufficient collapse of the tumor to embarrass the dissection. As this was carried down towards the base, the small veins in its vicinity were found very much enlarged and tortuous. Three of these were tied. Around the lower portion of the cyst there had been plastic inflammation sufficient to blend its surface intimately with the sheath of the vessels, upon opening which the carotid and its accompanying nerves were found free, but the vein was so closely adherent to that part of the sheath blended with the sac, that it was impossible to separate it. So firm was the union that (the venous coats being evidently softened by the inflammatory process) in the very careful attempts to liberate it with the finger and the handle of the scalpel, the vessel ruptured, and there was a most alarming gush of venous blood. This was instantly controlled by pressure, and but little time was lost in applying a ligature to the cardiac side. Being now secure against the entrance of air, sufficient pressure was made by the fingers of an assistant, on the distal side, to control the hæmorrhage, the opening in the sheath extended, and the vein carefully isolated from the accompanying artery and nerves to a point above its attachment to the tumor where it was tied, and divided just below the ligature as it was also just above the first point of ligation. The portion thus exsected was two and a half inches in length. The dissection was carefully continued down to the transverse process of the third cervical vertebra, to which the pedicle was firmly attached. Around this a smooth, well waxed, hempen twine was tied, the tumor separated with the knife, and removed from its bed. But one artery was tied, and that a very small one. After all oozing had ceased and the parts were somewhat glazed, the flaps were united by interrupted silver sutures, the ligatures emerging from the lower angle of the incision. Reaction came on slowly, but in eight hours was well established. For four days he had considerable fever, and complained much of headache and giddiness. Was delirious occasionally. On the fifth day the fever abated, and from this date he slowly but steadily improved. The greater portion of the wound united by first intention. There was considerable purulent discharge, but of a laudable character. The ligature around the pedicle came away on the 19th day, the others having separated previously. On the 28th day after the operation he was able to walk to my office, and the next to ride home in the cars, a distance of ten miles. At this time the wound was entirely healed, and he only complained of some stiffness of the neck and of a strange feeling in that side of the head. These symptoms passed away in a few weeks, and he is now a stout, healthy man, able to carry on his business as a farmer with as much ease as ever.

Immediately after the operation, he commenced taking tr. ferri muriat. 3 ss., every four hours, which he continued all the time that he was under my observation, combining it with quinia after the surgical fever had passed. While this was active he got a saline cathartic preceded by a mercurial, veratrum sufficient to control the heart's action, Dover's powder q. s. to procure rest; cool, effervescing draughts, etc. Beef-tea and gruel for the first five days, after which he was allowed milk, steak, chicken, and eggs, in moderate quantities.

In common, I suppose, with all my professional brethren, I was taught when a student, both by preceptor, professors, and the text-books, that the ligation of veins was a most hazardous procedure; and so emphatic and oft-repeated were the warnings given that I became thoroughly impressed with the idea that so great was the danger of pyæmia as the result of any such interference, that it was only justifiable in cases of extreme emergency, and for several years my practice was in conformity with this doctrine.

Of course when we ligate any vessel we desire and expect a certain amount of inflammation, being only anxious that it shall be of a character consistent with the exudation and complete organization of plastic material. In various conditions of impaired nutrition, and especially in toxæmia, we may fail to secure this result and have instead a purulent, or, what is much worse, an ichorous exudation, which, if it finds its way into the general circulation, seriously aggravates the toxæmic condition; but I doubt very much whether any valid reason can be given why this unfortunate form of inflammation *should* attack a ligated vein rather than a ligated artery, or whether a candid review of the experience of the profession would establish this *as the fact. If such inflammation occurs*, then the ichorous pus is much more likely to reach the general circulation and produce its deleterious results, if formed within a vein than if within an artery. For in the first it

mingles with the enlarging stream, and flows inwards without obstruction until it reaches the portal or pulmonary capillaries, whereas the current in the arteries is forcibly towards the surface; and thus we are more likely to have superficial abscesses as the result of arteritis, and visceral as the result of phlebitis; but that this form of inflammation is more likely to *occur* in veins than in arteries I very much question. I do not believe that *ligation* adds to the danger of pyæmia in the case of a *wounded* vein, or that any other than plastic inflammation follows in a healthy condition of the blood; always presuming, of course, that no poison has been communicated to the wound during the operation. In septic states of the blood all operations are dangerous, and those upon veins especially, as for the reason above stated, but in case of a wounded vein I do not believe that the *ligature* adds to the danger in any condition of the system. My opinions upon this subject have not been formed without much thought and observation. I have now ligated the internal jugular four times. Once in a case of attempted suicide, once in case of a deep seated cervical tumor removed before the class of 1866, in the Medical School of Maine, again in the removal of a bronchocele last summer, which case was reported in this journal, and in the case of exsection here recorded. In none of these were there any untoward results. I have ligated the femoral vein after amputations of the thigh in six instances. Four made good recoveries, and two died within a few hours after the operation. I have once ligated the axillary vein in a shoulder-joint amputation with good recovery. I have repeated the same procedure upon the anterior and posterior tibial veins with no ill effects. In many ligations made for varicosities of the saphenous and spermatic veins, for the cure of hæmorrhoidal tumors, "aneurism by anastomosis," etc., I have never seen any of the results of which I stood in so much fear years ago. If I have been more fortunate in my cases than some others, my experience is not so exceptional as to fail in demonstrating, at least to my own mind, the comparative safety of the operation. I am confident that in several instances, by thus saving a small amount of blood, I have turned the trembling scale in favor of the anæmic patient. I am equally confident, too, that years ago I lost patients that might have been saved, simply from reluctance to "tie veins." Frequently have I seen excellent surgeons, after an amputation, tie every bleeding artery with all haste, and hesitate to arrest by the same means the fatal loss of a few drachms or ounces because it came from a vein. I have no doubt that many lives were thus sacrificed during the late war.

PITTSFIELD, MASS., May, 1867.

PROF. BILLROTH.—After a long discussion over the various candidates, Professor Billroth, of Zurich, has been called to the chair of Surgery in the Vienna University, made vacant by the death of Professor Schuh. The *Medicinische Zeitung* remarks that there is but one voice as to the propriety of the choice. Before called to Zurich, Professor Billroth was an assistant to the famous Langenbeck in Berlin. He has written a work on Surgical Pathology and Therapeutics, which has reached a second edition. Pitha, Dumreicher, Patruban, Ulrich, Dittl, and Lorinser, together with the last acquisition, are now the surgical teachers in Vienna, who assist in maintaining the glory of that medical school which has so long enjoyed the highest reputation. There is perhaps no place in Europe where so many advantages are brought together for medical study as in Vienna.

Original Lectures.

AN INTERESTING CASE OF

VESICO-INTESTINAL FISTULA: DISCHARGE OF ASCARIS LUMBRICOIDES PER URETHRAM.

BEING REMARKS MADE ON THE PRESENTATION OF THE SPECIMEN TO THE N. Y. PATHOLOGICAL SOCIETY,

March 13, 1867,

By E. KRACKOWIZER, M.D.,

OF NEW YORK.

MR. PRESIDENT—I am going to show a specimen of great interest and rarity. Three or four weeks ago a medical friend in Schenectady informed me of a patient of his who had all the leading symptoms of vesico-intestinal fistula. I wrote to have him sent on to me, and he arrived here on the 25th of February. I gave him a little rest, and, as the case was to me quite an extraordinary one, I instituted as close an examination about the history of his life as I well knew how.

He was twenty-eight years of age, of medium size and strength, and of healthy parents. He did not know that anything had ailed him up to his eighth year; he was quite positive that up to that time he had no considerable sickness that had attracted his attention, or that was retained as important in the memory of his parents. When he was eight years old, and while on the street, he felt a queer sensation at the end of his penis, as if he desired to pass water. He made an attempt to do so, but without success. On looking down at the penis he discovered something protruding from the opening of the urethra, which he grasped with his fingers, and pulled it out. It proved to be a worm. He says it was still living. It was not preserved. Before that time he had no inconvenience from the bladder or bowels, except that he never remembers having had well formed solid stools, but always had two evacuations daily, which, although liquid, were of natural colour. From that time forward, he would have occasionally, at intervals of several weeks or months, a queer sensation about the penis or perineum, a little scalding sensation in passing water, and an inclination to urinate a little oftener than usual. This would last a day or two and then pass off.

At ten years of age he emigrated to this country, and when on board the vessel he experienced the same peculiar sensation which he had two years before, and in trying to pass his water a worm appeared at the head of the penis. The worm was extracted by his parents, and it is not known whether it was living at the time or not. This worm was not preserved. Seven years ago he again passed a worm from the urethra. This worm he put in a bottle with alcohol, and kept it. It was shown to me. It is an ascaris lumbricoides, between five and six inches long. A few days after that he noticed, for the first time, that a gritty substance passed through his urethra. He showed it to his physician, who did not express a decided opinion of its nature. But the patient had no doubt that it consisted of several seeds of whortleberries. The urine remained clear all the time. He did not have any more inconvenience, except perhaps at longer or shorter intervals, little unpleasant sensations along the urethra and perinæum; in fact, he was well enough four years ago to enlist in the army under Burnside's command. He was also under Hooker, and participated in the battle of Fredericksburgh, and in the first battles of the

Wilderness. He made forced marches with the army of the Potomac, participated in the battle of Gettysburgh, and, having there received a flesh wound in the leg, was transferred to a hospital in Baltimore. While there, he experienced some difficulty in passing his water, and voided some substances which appeared to be the seeds of berries. He was then discharged from service—more, however, on account of the wound of his leg than his urinary trouble. He returned to his home in Schenectady, and was well enough a year and a half ago to get married. Soon after this event, however, his urinary trouble increased upon him, and all the rational symptoms of stone in the bladder presented themselves. The passages from his bowels were always from that time liquid, abundant, and frequent. When he had a desire for a passage from his bowels, he had no control over himself, but was compelled to obey the summons immediately. These evacuations presented a very evident urinary odor, and sometimes consisted almost entirely of urine. The trouble in the urinary organs continued to increase; and he not only had all the symptoms of stone, but, superadded to these, there was no urine passed per urethram for days. Instead of this natural passage, there was great urinary tenesmus, followed by the voidance of mucus mixed with blood and shreds of coagulated fibrine, as we are wont to see it adhere to inflamed mucous membranes. His sufferings then became constant, yet they did not have much effect upon his constitution; he grew, it is true, somewhat thinner, but he never had any fever, and his appetite was good. He suffered principally at night in having his rest disturbed by the desire to evacuate his bowels, and also with urinary tenesmus.

When he came here I first satisfied myself concerning the character of the alvine evacuations. They were mostly derived from the secretions of the bowels, but they unmistakably contained urine. While he was here, he did not pass any water until the third day, when about half an ounce of perfectly clean urine was voided, at the bottom of which settled a moderate sediment of muco-purulent matter.

I regret that no microscopic examination of this urine was made with a view to determine the condition of the kidneys. I was prevented from examining it the first day, and the next day it was so much spoiled that I could not make anything out of it.

On the first of March, I had him put under the influence of chloroform, and went to work to make a systematic examination of his case. On introducing a steel sound I at once struck a hard substance; but I was in doubt whether I had a large single stone or several smaller ones. Immediately on introducing the sound, the beak passed over a very rough substance, exciting a grating sensation; and when introduced further into the bladder, it struck a smooth surface of considerable extent. The grating sensation occasioned by this procedure could be perceived by those standing next to the table. By making a rotatory movement of the sound, it seemed as if the smooth-faced stone slipped from one side of the beak to the other.

The next thing to determine was the connexion between the bladder and intestine. I suspected that this connexion must be between the smaller intestine and bladder, as there never had been the least show of any broken-down fœcal matter in the evacuations; they were, on the contrary, always liquid; and when they were allowed to stand, a bran-like sediment from epithelium and mucus, stained with bile, settled at the bottom of the vessel.

Moreover he never passed any flatus per urethram, an occurrence so characteristic, where the fistula exists between the bladder and the large intestines.

In order to make out a direct connexion between the bladder and gut, I thought it well to inject some colored substance into the organ and watch the effect There being no other available coloring substance at hand, I employed some wash-blueing, under the impression that it was composed of the cyanuro-cyanide of iron. I made a dilute solution of this, and while the anus was distended, I injected twelve ounces into the bladder; but when I opened the stopcock of the catheter so as to allow the liquid in that organ to escape, none came. The injection then must have left the bladder immediately after being injected; it seemed strange that none came from the bowel. An examination was made as high up as it was possible to make it, while the anus was distended with Sims' speculum, but no opening into the gut was discovered; no liquid was seen to dribble out from the walls of the rectum, nor did the finger reach anything to determine the existence of a fistula; in fact the mucous membrane of the rectum seemed so far perfectly normal.

I charged the attendant to mark particularly when colored stools should appear. The injection was made at one, and at three the first passage came, and several others at intervals afterwards; all of these were separated one from the other as soon as voided, but no color was found in any. This circumstance at first appeared strange, but when I afterwards learned that the blueing was composed of indigo simply, I explained the non-appearance of color by the rapid bleaching which that substance underwent in contact with the ammonia, the presence of which in the stools was easily detected by the smell. To be sure that this explanation was correct, I filled a tumbler with a recent fluid exacuation from the bowels, and added a small quantity of the washing blue. The bluish color which it imparted to the liquid disappeared in a few minutes, leaving the color as it was before the addition of the washing-blue.

Two days subsequent to this, I took the common writing ink diluted, and injected six ounces of it into the bladder. The stopcock of the catheter being opened as two days previously, no fluid escaped from its extremity, but about ten minutes after, however, the patient had a stool which showed some of the color; in the course of two hours more another stool was colored nearly as dark as the injection itself; in two hours more another stool contained the color, but not so intense, and four hours after the injection the evacuation had its usual brown appearance. This fact corroborated the opinion which I had previously held, that the fistula was high up, probably between the small intestines and bladder. This being the case it was impossible to devise any rational plan to treat the fistula, but the only indication to fulfil was to relieve the patient of the stones in the bladder.

While the patient was under chloroform I could feel a stone behind the prostate, and somewhat overlapping the upper and posterior part of the gland.

Four days after the first examination, and two days after the second injection, the operation was made in the usual manner by the lateral incision. As soon as the prostate was incised, the staff was withdrawn. When I afterwards introduced my finger I at once felt, as I thought, small rough fragments in the wound, which I grasped and removed. In the bladder there were found in all nine stones, five large and four smaller ones.

After the bladder was emptied, my attention was directed to the finding of the vesical entrance to the fistula: I discovered towards the right and a little above, as I thought, of the trigonum, a funnel-shaped recess with a concave, prominent, upper border, with the

lower border slanting off towards the trigonum Lieutaudii. I tried to introduce a probe into this hole, but was unable at first to do so, and fearing that I might do damage to the parts in any further attempts, I desisted.

The patient after the operation felt greatly relieved. and went on for the first three days very satisfactorily, The only thing that I did not like was his listlessness; he was, however, perfectly rational and had no fever. During this time all his water passed through the wound. At the end of the third day he had fæcal evacuations which were nearly liquid.

On the fourth day he had quite a large stercoraceous evacuation from the bowels, of almost pultaceous consistency. Its odor and color were normal.

On the fifth day, he seemed even more drowsy; his pulse was high and feeble, he had felt chilly several times the preceding night. The skin felt rather cool, the tongue dryish. The respiration was normal. He complained of sharp pain in the hypogastrium. There was no tympanitis, in fact the abdominal walls felt very rigid, a condition hardly ever wanting in such who for urinary tenesmus have had the muscles of the prelum abdominale constantly taxed. The wound at the perinæum looked healthy, and the urine dribbled from it as from the day of the operation. He never vomited, and although the pain was bearable under moderate doses of opium, he grew weaker and weaker during the day, and expired March 11, at one o'clock A.M., five and a half days after the operation.

The post-mortem was made twelve hours after death. On opening the abdominal cavity, and throwing back the omentum, all the contents of the abdomen, as far as they could be seen, looked perfectly natural; there was no injection of the capillary vessels of the peritoneum except near the caput coli, but there was no exudation. On pushing back the small intestines, which brought the cæcum, sigmoid flexure, and entrance to the pelvis into view, the manner in which the fistula was established was at once explained. The vermiform process was seen to dip down straight over the rim into the pelvis, and be attached to the posterior and lateral aspect of the bladder by old adhesions, which in their turn spread towards the right side of the rectum, and strong bands of old adhesions passed from the sigmoid flexure towards the parietal peritoneum on the left side, showing that extensive pelvic peritonitis had occurred at some time during his life. By compressing the lower end of the ilium, and making pressure upon the caput coli, intestinal gases could be thrown into the bladder.

While handling the abdominal organs, three or four ounces of a well colored, thick, and odorless matter oozed up between the bladder and rectum. I did not see the exact spot whence it came, but had no doubt that it came from an extra-peritoneal abscess that had burst in the peritoneal cavity low down in the pelvis by the post-mortem handling of the parts. With a view not to spoil the specimen, while I took out all the pelvic viscera with the perinæum, anus, and penis below, the cæcum, with the end of the ilium, and a goodly portion of the S. Romaum above, I was very careful to get the peritoneal lining of the small pelvis intact. I divided the peritoneum by a circular incision along the rim of the pelvis, and peeled it off from the surrounding connective tissue. In doing so there were found in the areolar tissue of the cavity of the sacrum three or four small abscesses, none containing more than a thimbleful of creamy yellow, inodorous pus. The iliac and hypogastric veins with their branches contained liquid blood, and there was not the first beginning of a thrombus in any of them.

All the parts in their connexion with the kidneys by the ureters being spread on a table, the vermiform process was found adherent not by its extremity, but about three-fourths of an inch from it.

The bladder being split open in front by a longitudinal incision, did not show a thickening of its walls. Its mucous membrane was of a bright slate color, and moderately congested. At the neck of the bladder was seen a large, sinuous ulcer, nearly encircling its whole circumference, and deeper on its left side. In this, probably, the four rough, small calculi were lodged, and if so, it is accounted for why the beak of the instrument at times encountered some difficulty in entering the bladder, and why on this spot an unusually harsh, grating sound was produced.

The posterior angle of the cut in the prostatic portion stops just short of the anterior ragged border of this ulcer. The wound from the operation is smooth in its whole extent, and leaves about one-eighth of an inch of the left lobe of the prostate gland undivided. Nowhere in the neighborhood of the wound, or exteriorly to the capsule of the prostate, or in the connective tissue between the fundus of the bladder and the rectum, the least trace of infiltration of urine, or sloughing, or an abscess can be found.

One inch above the entrance of the right ureter into the bladder, a smooth-bordered opening is seen, admitting readily the end of a conical elastic bougie, which enters at once in the vermiform process there where it adheres to the body of the bladder. By giving the bougie an upward and outward direction, its end emerges after having trans-coursed the vermiform process in the cavity of the cæcum.

About one-eighth of an inch below this hole there is another, smaller, circular opening, which does not communicate with the vermiform process, but ends blind at the depth of a couple of lines.

The mucous membrane of the large intestines, from the cæcum down to the anus, has not undergone the least change from the urine.

The kidneys were somewhat larger and flaccid. Their capsules peeled off readily, leaving here and there small shreds of the cortical substance adherent to them. The surface of the kidneys was not smooth, but puckered in consequence of irregular depressions, caused by shrinkage of the cortical substance from atrophy on different spots.

On cutting them open, the cortical substance was seen reduced in bulk, forming here and there only a thin layer over the base of the pyramids.

On the surface of the left kidneys there was one small abscess, the size of a small hempseed, containing thick yellow pus.

The calices and pelves of both kidneys were dilated, those of the right kidney more so than those of the left one. Their mucous lining had a lurid port-wine color, which, on closer inspection, was seen to be produced by a rich arborescence of the smaller blood-vessels. The pelves held in their cavities a small quantity of turbid, floccular urine.

The peritoneal lining of the pelvic cavity was found in its whole extent fully intact, its surface smooth and glossy. There was nowhere a communication by ulceration or by an artificial rent with the subjacent connective tissue.

I have stated above, that along the sacrum there were in the extra-peritoneal connective tissue three or four small abscesses. They were filled with as much matter as they could hold, and nowhere else could a cavity be detected of a size to contain three or four ounces of matter that welled up from the bottom of the pelvis during the progress of the post-mortem examination, even if a communication between the peritoneal

sac and its surroundings had existed. But there was no lesion of the peritoneum, and its surface was just as normal as could be seen when it is not the seat of morbid action.

I cannot escape then the conclusion that the matter was the secretion of the peritoneal surface itself.

Although the patient was rather drowsy after the operation, and the kidneys were evidently the prey of pretty far advanced Bright's disease, yet there were no well marked symptoms of uræmia. But the symptoms of pelvic peritonitis, coming on rapidly on the fifth day after the operation, were well pronounced.

If I take in connexion with them the scattered abscesses in the sacral region, and the small abscess in the left kidney, the least improbable explanation seems to me to be, that pyæmia commenced on the fifth day, establishing purulent depots on the enumerated localities.

That the peritoneal surface appeared normal, notwithstanding the purulent secretion, seems surprising, but not more so than in other cases of pyæmia, where we see large purulent secretions in the joints establish themselves in the course of a few hours, and yet the post-mortem fails to detect the least injection, the least roughening of the synovial membrane, the smallest shred of fibrinous exudation, the least erosion of the incrustating cartilage.

Several other interesting questions come up in connexion with this case for solution. In the first place, at what time did this connexion between the vermiform process and bladder take place? Now, we have evidences of the existence of quite an extensive peritoneal inflammation existing before the last illness; here you have small bands from the side where the fistula is to the rectum, here others between the rectum and bladder, and from the sigmoid flexure there were even larger and stouter bands running towards the peritoneum. He is very distinct in his statement, that he never had any trouble, that he had never been "laid up" until the time I refer to, and his parents were unable to recollect any severe illness in his infancy; the first thing wrong that was noticed was the appearance of the worm per urethram. I do not think it impossible, that at a time considerably antecedent to the appearance of the worm, he passed through a pelvic peritonitis, which fixed the vermiform process on the lateral posterior aspect of the bladder, and that later a small foreign substance lodged there, caused irritation and inflammation, and established a communication with the bladder by ulceration. It is well known that these local peritoneal inflammations do sometimes occur, and do no more for the time than agglutinate adjacent parts, and the physician is not unfrequently surprised by the explosion of a fatal peritonitis, starting from a subsequent ulceration.

The next question to decide is as to the time when this fistulous connexion between the vermiform process and the bladder took place? Most certainly it has existed since his eighth year, for then the first worm was voided from the bladder. But, how is it that he did not suffer from this communication before, even had it then existed? I think the true explanation is this:—The vermiform process, by its adhesion to the bladder, was pretty tightly stretched. The communication with the bladder was not at its extremity, but about three-quarters of an inch from it. The fistulous track in this manner had a perpendicular direction towards the axis of the processus. Moreover, the inosculation between the opening in the vermiform process, and the opening in the bladder, was not immediate, but the fistulous track between the two cavities had an appreciable length. In fact, when the bougie was introduced from the side of the bladder in the vermiform process, in a direct line, it was there arrested, and it was necessary to give it an outward and upward turn to carry it on easily through the vermiform process into the cæcum.

It will be perceived that all these circumstances cooperated to establish a valvular occlusion, which never by the fluid contents of the bowels, and only accidentally and occasionally by solid bodies, like worms, seeds of berries, was overcome.

As long as there was no impediment in the bladder, by which the voiding of the accumulated urine per urethram was made difficult or impossible, the said valvular arrangement at the fistula set itself against a regurgitation of the urine filling the bladder into the vermiform process.

The occasional intrusion of foreign bodies from the gut in the bladder at first happily was got rid of by their immediate expulsion per urethram.

But when once stones in the bladder commenced to form (undoubtedly by such erratic blocks from the bowels furnishing the nuclei), this fortunate coöperation for a valvular occlusion was disturbed, and the order of things indeed reversed.

When the voiding of the bladder became difficult, partly by the mechanical occlusion from the stones, partly by spasmodic contraction at the neck, the urine accumulated in the bladder, being under equal pressure from all sides by the action of the detrusores vesicæ, sought an outlet where there was the point of least resistance. And this was indeed there where the entrance to the vesico-intestinal fistula was located. In point of fact the fistula became a vicarious urethra, through which the bladder expelled the urine as it dribbled down from the ureters.

So it is explained, why the last one and one-half years, since the urinary trouble commenced, never any fluid secretion from the bowels appeared per urethram, and why only small quantities of urine, sometimes only in intervals of three to four days, passed by the act of micturition. It was mainly forced into the bowel, and there produced by its irritation an abundant secretion, and a more rapid contraction, with a view to expel the contents of the viscus. He always passed large quantities from his bowels, and during all the time he was under my observation he never passed less than two chamber-potfuls in a day; of this probably about two pints was pure urine.

The next question, and the most important one, is this:—Could he have been relieved if the operation for stone had succeeded? If the complications—Bright's disease and ulceration of the bladder, which I look upon as the disposing cause to the fatal pyæmia—had not existed, there is no reason why the operation of lithotomy should not have been successful. If it had been so, I do not see why the patient should not have had a quiet time again, just as much as he enjoyed from his eighth to his twenty-sixth year, when stones in the bladder commenced to form.

That any rational plan could be devised to close the fistula I do not believe.

As objects of surgical interference, cases of intestino-vesical fistula must be divided into two distinct groups.

The *first* group, comprising cases in which the fistula exists between the bladder and the rectum, and can be seen and reached, permit surgical treatment.

Of the *second* class, where the fistula exists between the bladder and any section of the intestines down to that part of the rectum which already receives a peritoneal investment, I think it must be said that it is beyond the reach of art.

First, the exact situation of the fistula must always

remain rather a matter of surmise, although the statistics indicate the cæcum as that part of the intestines which, by its not uncommon lesions, is most frequently the organ implicated.

But even granted that the exact site of the fistula could be diagnosticated, how could it be attacked except by opening the abdomen, detaching both viscera from each other, and closing each fistulous opening separately with sutures? That such a procedure has the mark of fatality broadly stamped on it, it is unnecessary to dwell upon.

I refrain, too, from criticising the fantastic plan of a French surgeon (Barbier), who proposes to make a temporary artificial anus at the cæcum, and to introduce through it a metallic tube, reaching somewhat above the valvula Bauhini, through which the fæces from the ilium would be led past the fistula, which, ceasing to be the conduit of stercoraceous matter, might then close. After which the artificial anus might be closed also. The objections are so manifest, that I forbear to enter on their enumeration.

Quite distinct in scope and technicism from Barbier's, is the plan to make an artificial anus for the relief of vesico-intestinal fistula, pursued by Pennell* and T. Holmes†. Both these surgeons had to do with cases in which the intestinal entrance of the fistula could not be detected by rectal examination. But both cases showed symptoms which made it probable that the intestinal end of the fistula was below the region in which, by Callisen-Amussat's operation, an artificial anus is established. Both these gentlemen succeeded in leading the contents of the bowels out through an artificial anus in the left lumbar region, so that they could no more engage in the fistula and reach the bladder. In Pennell's case the patient did well, and lived for many years. I am not able to find out whether the fistula healed and the artificial anus closed. In Holmes's case, the patient was entirely relieved—for better than one year, I believe—from all the symptoms consequent upon fæces getting into the bladder; when these very same troubles reappeared, and the patient succumbed. The autopsy revealed the fact, that some time after colotomy by adhesion and ulceration a new fistula had formed, between the cæcum and the bladder, the deleterious effects of which, of course, could not be warded off by the artificial anus in the left lumbar region. The specimen was shown by T. Holmes in the London Pathological Society.

Although vesico-intestinal fistula is one of the rarer lesions, yet there is a goodly number of cases on record. But cases in which by it the possibility arose for intestinal worms to get into the bladder and be expelled per urethram, are exceedingly scarce. C. Davaine, in his "Traité des Entozoaires et des Maladies Vermineuses," Paris, 1860, has collected only 14 cases.

In two of these the worms reached the bladder by a vesico-rectal fistula.

In three cases the history is quite incomplete.

In one case it is mentioned that death was imminent.

In one case no post-mortem examination was made.

In five cases it is mentioned that the troubles diminished or ceased after the expulsion of worms. In two of these cases the relief seemed a lasting one. If we look at them by the light which our case furnishes, I think we may greatly doubt that the fistula had healed radically.

In only two cases the post-mortem result is reported.

The case of Dr. William Kingdon (*Med. Chirurg. Review*, July, 1842) bears such a striking similarity to mine, that I think it interesting to re-state it here:

A boy of seven years, at the commencement of the year 1836, suffered from the retention of urine for more than eight days, after which an ascaris lumbricoides presented itself at the meatus urinarius, and was pulled out by the child himself. One year afterwards the same thing occurred, and the mother extracted a worm from the urethra. Worms presented themselves successively at the opening of the urethra six months later, then in October, 1838, and in January and April, 1839. The passing of several worms per anum, violent pains in the region of the bladder, purulent urine, which afterwards passed with the stools, high and constant fever, transient loss of sight, and extreme exhaustion, were the leading symptoms, until death occurred, November 15, 1839.

Post-mortem Examination.—The vermiform process, instead of occupying its usual place, dipped down in the small pelvis, and about one inch from its extremity adhered closely to the upper and lateral portion of the bladder, a little above the junction of the ureter with the bladder. The bladder itself was small and contracted around a hard body that was recognised as a stone, one and a half inches long and two and three-fourths inches in circumference. The walls of the bladder were very much thickened, and opposed themselves almost entirely to the passage of the urine in the direction of the urethra. The mucous membrane of the bladder was ulcerated on two spots, and in a direct line with the orifice of the ureter, and a little above it were two fistulous openings, separated by a very narrow spur, which communicated with the interior of the vermiform process. Both ureters were very much enlarged, and both kidneys, more voluminous than normal, were so completely filled with pus, that hardly a trace of healthy tissue remained.

Dr. Kingdon divided the stone with care, and found in its centre a large pin. The stone had not been recognised during life.

Description of the Stones.—There were five smooth, and four rough ones. Dr. L. Voss, who assisted at the operation, tells me there was a very small fifth rough one, which was lost. The smooth ones had a chalk-white color; the largest was one and a half inches long, one and one-fourth inches wide, and one inch thick. It was oval, and only one side showed a little evenness, from attrition. The other four smooth stones, of which the smallest was only half an inch long and about three-eighths of an inch in width and thickness, while the remaining three were of intermediate size between the smallest and largest—had all originally a round or oval shape; but each one had the sphericity broken by two planes meeting at a right angle, caused by the grinding of the stones one against the other. The four stones, by putting them together, the corresponding planes facing each other, gave evidence that their relative position must have been all but permanent. The larger stone must have lodged on top of this cyclopic masonwork.

The four rough stones were quite small; but each one was studded on its surface with warty protuberances. Each two formed a set in this manner—that each stone offers a small polished surface that corresponds most exactly with a similar surface of its mate. The fit was as perfect as between an axle and its box. This circumstance makes it evident that each set of two stones had an independent, well secured spot in which they were held so fast that only the most insignificant sliding motion between each two was permitted. The ulcer at the neck of the bladder with the larger excavation

* A case of stricture of the rectum, wherein an artificial anus was successfully established in the lumbar region. By J. Wilson Croker Pennell, *Med. Chir. Transactions*. 1850. Vol. 33.

† A case of lumbar colotomy, successfully performed for the relief of vesico-intestinal fistula. By T. Holmes, Ass. Surg. St. George's Hospital, London. *Med. Chir. Transactions*. 1866. Vol. 49.

on its left, and the smaller one on its right side, was undoubtedly the bed for the two sets of stonelets.

Dr. J. Pramann, who had the kindness to make the sections of the stones, gives the weight of them as follows:

Smooth stones,	1 gr. 177	Rough stones,	6 gr. 29
" "	2 " 143	" "	6 " 10
" "	3 " 106	" "	8 " 6
" "	4 " 80	" "	9 " 5
" "	5 " 22		
	528		50

Together, gr. 578.

The section of the stones so far disappointed my expectations that the nuclei did not show anything characteristic which would lead one to suspect that they had immigrated from the intestines. The largest stone contained three nuclei, so that at one time three separate stones must have existed, which by ulterior earthy deposits coalesced in one. The next largest stone had its nucleus quite eccentric, and contained a large cavity. Compact and porous layers, in irregular alternations, characterized each stone. Of the rough stones, only the largest admitted of being cut in two. Its structure was exceedingly porous.

The material of all the stones was the same—phosphate of lime and a liberal admixture of carbonate of lime.

Progress of Medical Science.

Nitro-Muriatic Acid in Asthma.—Dr. B. F. Records reports a case (*Medical and Surgical Reporter*) which he considers to be Spasmodic Asthma cured by the internal and external administration of this acid. The dose was six drops in half a tumblerful of sweetened water every eight hours. Ten drops of the same in a gill of water were applied locally in the region of the liver by means of a saturated flannel cloth. He does not state how long it took to effect the surprising result.

Expectoration of a Minié Ball.—Dr. A. Geiger, Dayton, Ohio, publishes in a recent number of the *Medical and Surgical Reporter* the case of a soldier who was wounded in the chest on the 7th of April, 1864, which shows a rather remarkable circumstance in connexion with the subsequent appearance of the missile. The ball entered at the lower margin of the seventh rib, penetrating the chest, and lodged. He bled severely at the time, but refused to be carried to the hospital, and remained with his comrades in camp, and after five days started on horseback with Gen. Stoneman's brigade into Georgia, South Carolina, etc., and continued with his regiment until the close of the war. He states that after the healing of the wound externally, he did not experience much inconvenience, except occasional shortness of breath, and inability to perform active exercise, such as fast walking, running, etc. After being discharged from the army, he returned home, and engaged in work at his trade, that of a carpenter, and continued to enjoy tolerable good health until some time in September, 1866, he contracted by exposure a severe cold, since which time he has had some cough, and frequent expectoration of blood; also at times complete aphonia, with sense of suffocation. One of these attacks was so severe as to produce spasms and insensibility, which continued for several hours. Oftentimes, during a severe fit of coughing, accompanied sometimes by vomiting, he would feel the presence of a hard body in the windpipe, which he could almost at the time cough up.

On the 26th day of March, 1867, after having been at work during the forenoon, he felt so unwell at noon that he returned home, and in a short time afterwards was taken with a severe fit of coughing, and soon expectorated a "Minié ball," weighing three fourths of an ounce, and the one that nearly three years previous had entered the left side. The ball was covered entire with a tough mucous coat, and the small cavity at the base was filled with pus. Considerable hæmorrhage followed the expectoration of the ball, but the relief he experienced was so great, that he rejoiced to be rid of his unpleasant companion that for so long a time had been the occasion of so much discomfort.

Absinthe.—The French Senate lately received a petition that some steps should be taken by the Government to prevent the sale and consumption of absinthe. Baron Charles Dupin read a very interesting report on this petition. He pointed out that the mountains of the French Jura and the town of Besançon produced it in sufficient quantities to supply the whole of the French market. It produced insanity after a certain time; and the ravages produced by it in the French army were such that Marshal Forey had prohibited its sale at the military canteens throughout his command. Baron Dupin suggested the imposition of a heavy tax as the best way of checking its consumption, which, if it went on at its present rate, would have quite as pernicious an influence on the population of France as opium had on that of China. He recommended that the petition be referred to the Government for consideration, and this motion was agreed to without a division.

How to Syringe the Ear.—In order that a stream of water may reach thoroughly the bottom of the ear, it is necessary first that the way that leads to it be straightened as far as possible. For this purpose take hold of the auriculum, or external portion of the ear, and draw it pretty firmly directly upwards, and in this way the upper and lower wall are brought as nearly as possible into straight lines. Holding the ear in this position with the left hand, take the syringe in the right, and inject the water *gently*, yet with a *little* force, into the ear, directing the point, which should be introduced a little into the external orifice of the meatus, inwards, a little downwards, and forwards in the general direction of the tube. Of course a cup must be pressed against the face, beneath the tragus, in order to catch the water as it escapes. It is recommended to have two cups, one to contain the clean water to be injected, and the other to catch it. The best syringe for the ear that I have ever seen, is what is known as the Ear Syringe, made of gutta-percha, which is very light and very convenient, as well as durable. The syringing operation is to be continued till its object is attained, which is always *cleanliness*.

Better use simple warm water, without any soap, which is supposed to irritate considerably. It may be repeated as often as necessary for the attainment of the object in view. Some persons are not affected at all by syringing the ear, while others, who are in perfect health, and who are anything else but *nervous*, faint from it.—Dr. E. Williams, *Cin. Lancet and Observer*.

Detection of Blood-Stains.—M. Blondeau, of Nancy, has sent a memoir to the Academy of Sciences, relative to the detection of stains of blood upon linen in the case of legal surgery. All persons occupied in legal medicine comprehend the great interest attached to such inquiries; for after the linen has been washed the stains resemble very much stains of rust or iron-mould, or marks which certain organic acids or vegetable coloring matters would leave. These are the principal cha-

racters indicated by the author: 1. Stains of rust or iron-mould are clear and dull; blood-stains are of a deeper color, and shining. 2. If the linen be wetted with hydrochloric acid, the iron-mould is dissolved, while blood-stains remain unaltered. In the former, the presence of iron is at once indicated, but not so in the latter. 3. The stains of acid fruits with iron are hygrometric and soluble in water. 4. The microscope should be employed, in order to recognise directly the globules of blood detached from the linen and dissolved in oil.—*Brit. Med. Jour.*

Cod-Liver Oil.—M. Naumann has arrived at the following conclusions concerning the physical constituents and the physiological action of cod-liver oil: 1. Cod-liver oil travels through dry or moist animal membranes with much greater facility than do any of the other fatty oils. 2. Brown cod-liver oil possesses this property in the most marked degree. 3. The cod-liver oil which has been the most completely deprived of its biliary principles, almost entirely loses its power of penetration, and acts only in the same manner as the other kinds of oil. 4. Cod-liver so deprived of its biliary matter can regain its power of penetration by the addition of bile to it. 5. The other kinds of oil treated in the same matter with bile, acquire the power of more easily traversing the animal membranes than they previously possessed. The fat of cod-liver is more easy of absorption than any other fat.

An Anodyne Formula.—The following formula is recommended for combining chloroform and morphia for internal administration: One part, by weight, of morphia is dissolved in two parts of rectified wine-vinegar, and twenty parts of rectified spirit of wine; and the solution, when cold, is mixed with eighty parts of chloroform. One drop contains the three-hundredth part of a grain of morphia. The dose for a child is two to fifteen drops; for an adult, thirty to forty drops. It is said to give relief in most painful affections much more quickly and certainly than morphia alone, and to leave none of the unpleasant after-effects of opium. The subcutaneous injection of morphia during chloroform narcosis, is strongly advocated in all those cases where it is desirable to maintain the state of unconsciousness for a lengthened period.

Prejudices concerning Breast Milk.—M. Devergie and M. Boudet have been carrying on a discussion relative to ill-regulated nourishment of infants, which is of some practical interest. M. Devergie asserted that nine months' milk was too rich for a new-born infant. M. Boudet declares that chemical analysis demonstrates that, from the first to the eighteenth month, the milk scarcely changes at all. It follows that the supposed danger of feeding a new-born infant with the milk of a woman who has been nursing twelve months is chimerical. M. Boudet also combats the wide-spread opinion, that a new-born infant rejuvenates the nurse's milk.—*British Medical Jour.*

Blanching of the Hair.—Physiologists have been at a loss to account for the sudden whitening of the hair which is known to be produced by intense and sudden terror or profound grief. Mr. Erasmus Wilson, in a paper recently read at the Royal Society, threw considerable light upon the question. The paper was founded on a case apparently unique, in which every hair of the head was colored alternately brown and white from end to end. The white segments were about half the length of the brown, the two together measuring about one-third of a line. Mr. Wilson suggested the possibility of the brown portion representing the day growth of the hair, and the white portion the night growth, and this opinion was corroborated by the remarks of Dr. Sharpey and others of the Fellows who took part in the discussion which followed the reading. Under the microscope the colors of the hair were reversed—the brown became light and transparent, the white opaque and dark; and it was further obvious that the opacity of the white portion was due to a vast accumulation of air-globules packed closely together in the fibrous structure of the hair, as well as in the medulla. There was no absence of pigment, but the accumulation of air-globules veiled and obscured the normal color and structure. Mr. Wilson observed that, as the alteration in structure, which gave rise to the altered color, evidently arose in a very short period, probably less than a day, the occurrence of a similar change throughout the entire length of the shaft would explain those remarkable instances, of which so many are on record, of sudden blanching of the hair; and he ventured to suggest that during the prevalence of a violent nervous shock the normal fluids of the hair might be drawn inwards towards the body, in unison with the generally contracted and collapsed state of the surface, and that the vacuities left by this process of exhaustion might be suddenly filled with atmospheric air. Dr. Sharpey mentioned a recent example of sudden blanching of the hair, which had been observed by Dr. Landois, of Greifswalde, as reported in Virchow's Archiv, and which was ascertained to be due to accumulation of air-globules in the fibrous substance of the hair.—*Lancet.*

On the Examination of Diabetic Urine: New Reagent for Glucose.—After noticing the several reagents used, and pointing out their special inconveniences, MM. Francqui and Van de Vyvere propose a solution containing oxide of bismuth. The following process cannot, they say, give rise to any fallacy. Prepare the reagent by precipitating a solution of acid nitrate of bismuth by a great excess of caustic potash, and pour a solution, drop by drop, into the moderately heated solution, until the precipitated hydrate of bismuth is completely redissolved. To recognise a diabetic urine, heat a portion with the above solution. After a few minutes' ebullition, the urine becomes brown, and metallic bismuth is then precipitated in the form of a black powder of crystalline appearance, adherent to the glass if glucose be present. They have satisfied themselves that the principles contained in normal urine, such as urea and uric acid, do not precipitate the above reagent. Albumen only causes a brown color and a slight turbidity, which they consider to be due to the formation of sulphide of bismuth. Sulphuretted urines also give a black precipitate in a solution of oxide of bismuth in potash and tartaric acid; but this reaction cannot be confounded with that caused by glucose. It is, besides, easy to recognise and (if desired) to separate the albumen. Thus, on bringing to ebullition the urine of a person suffering from Bright's disease, the liquid becomes turbid, opalescent, and deposits coagulated albumen. Sulphides and sulphuretted hydrogen are easily recognised by means of hydrate of lead, which these compounds darken.—*Gazette Médicale* and *Chemical News.*

Pomade for Chilblains.—In an article on chilblains, by M. Guersant, that surgeon states that the following ointment is often very valuable: Lard, 30 parts; iodide of potassium, 1 part; tincture of iodine, 1 part.

Gonorrhœal Ophthalmia.—M. Gosselin strongly recommends frequent injections of highly alcoholized water under the lids in cases of gonorrhœal ophthalmia.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

GEORGE F. SHRADY, M.D., EDITOR.

THE EXAMINATION FOR ADMISSION TO OUR MEDICAL SCHOOLS.

THERE are many points connected with the action recently taken by the Convention of Medical Teachers which are deserving of notice; but not the least among these is that relating to the necessity of a preliminary education on the part of all applicants for matriculation. It is too well known that under the existing system of admitting students to our medical colleges, the only desire seems to be to have a large class, and swell the treasurer's account; every means is taken to attract young men to the study of medicine, without taking into account their fitness for the undertaking. The result of all this is, that the number of students is in the aggregate very large, and the amount of brains they represent very small. There have been no measures adopted heretofore to ascertain the fitness of any would-be student of medicine for his prospective tasks in a medical college, other than the ability to write his name legibly upon the matriculation book. By that act he becomes a matriculant of the college, becomes accountable for the fees of his tuition, and that is all that is required of him.

The wisdom of exacting some standard of qualification on the part of all applicants for medical studies has never been doubted, but the policy of acting upon such a belief by those whose interests were directly at stake, has been quite another thing. The faculties of our colleges have repeatedly, almost to a man, admitted the necessity of preliminary education; but at the same time they tell us that any compulsory measures in regard to it would be highly impracticable. They are well aware, in making such an assertion, that the cause of medical science will not suffer so much as the medical schools; they know full well that the number of those in the class who have graduated from literary institutions is comparatively very small, and that those who are otherwise well qualified to commence attendance upon lectures, is perhaps still smaller. Hence, if any reasonable demand were made upon the applicants, the class would dwindle down to a very insignificant number. This we must admit, in a pecuniary point of view, is an all-powerful reason for so much of the apathy which has instilled itself into all those measures contemplating reforms in medical education.

Another assigned reason for neglecting to call for satisfactory evidences of fitness for the commencement of the study of medicine, is the want of some agreed standard to measure such qualifications by the adoption of a rule that could be practical, and that could be enforced without crowding out many worthy and competent aspirants for service in our ranks. The unfairness of compelling every applicant to show a literary diploma, has been too obvious; but the question as to how much should actually be required, has long been an open one. The recent decision of the convention upon this point, now appeals to the common sense of every faculty. The standard is by no means too high, and is certainly low enough for a fair beginning. All reasonable objection to its general adoption would seem, at least upon the ground of feasibility, now to be done away with.

The next question, as to how the examinations for admission should be carried on, is another one of great importance. Here again, the stringency of even this simple examination is so apt to affect the interests of the college, in regard to the size of the class, that the teachers themselves would hardly be considered, on general principles, as very impartial examiners. Much better would it be for those who have no interests at stake, to undertake this task; in other words, let it be entrusted to those who are not connected in a professorial way with the college. Every institution can very readily select some of the many well educated young physicians who have a taste for literary and scientific pursuits, to undertake this labor for the very honor of being known as members of the examining board of the college. The work would be by no means arduous, as it would only relate to such of the candidates who were unable to show a diploma from a literary institution.

The proper manner of conducting these examinations, in giving a free entry to those who had regularly received a degree of bachelor of arts, would eventually tend to encourage previous graduation from literary institutions; and young men would by and by consider it as necessary and as important to undergo such a training before studying medicine, as they now do to study for the ministry. In order to encourage such a course, it might be expedient, at least for the time, to place a premium upon a literary diploma, by even shortening to its possessors the regular attendance upon lectures, making the term six months, or even a year less. This, considering the great disparity of intellectual culture between those who have and have not been favored with a literary education, would certainly be allowable.

Again, the adoption of a system of preparatory examination would have another good effect in raising medical colleges in the estimation of young men, and

coaxing many an ambitious one into the study of medicine, because the lists were not unworthily entered. Our literary colleges compel all applicants to undergo a preparatory test, and the consequence is, every fortunate one who is able to enter, feels proud of the distinction. The more rigid the preparatory examinations are, the more eager do the applicants seem to be for an admission. This fact must also have its due significance, when applied to our medical colleges, and may be taken in evidence against the assertion that the number of applicants may fall off when even a nominal examination stands in the way of their admission.

Now that we have agreed upon a standard of acquirements, it remains to be seen whether the various colleges throughout the country will see fit to adopt not only the recommendations of the Teachers' Convention, but of the American Medical Association, and if not, it will be interesting to hear their excuses for a failure to comply.

But when are these suggestions to be carried into effect? Obviously the sooner the better. All reasonable endeavor on the part of the committee should be made to bring about the concerted action of the colleges, and we see no good reason why each college cannot prepare itself to announce, by the coming fall, that preliminary examinations would be enforced upon all new applicants for attendance upon lectures.

"Mr. Stephen Buckland, in the current number of *Fraser*, gives a startling account of the nature of the supply of milk to the inhabitants of New York." * * * * After the details of the swill-milk distilleries are given, with which our readers are quite familiar, the editor of the *Medical Times and Gazette* proceeds:

"It is from such dairies that New York is *exclusively* supplied with milk; for, although public opinion is occasionally excited against them, they have, in fact, secured the monopoly of the entire supply."

We hardly know whether to pity or blame the ignorance of our British medical brethren as to how we get on in New York. This article is, in point of reliability of statement, about on a par with the recent burlesque, entitled "An Englishman's Visit to America during the War," in which the traveller supposes New York to be in a state of rebellion, on seeing the hack-drivers who meet him on landing, and gets ready to shoot buffaloes and Indians on reaching the Park, etc., etc. Be it known to our friends of the *London Medical Times and Gazette*, that although distillery milk is probably used in New York, by far the greater portion of our people, who are American enough to prefer milk to whiskey and Alsop's bitter ale, drink milk from cows which feed in Orange and Westchester County pasturages, which are miles away from distilleries.

That it is diluted, we cannot deny, but with water. We also admit the existence and use of distillery milk; but we must protest against such wholesale statements as those which we have quoted, from our usually intelligent and truth-speaking neighbors.

Reviews.

Transactions of the American Ophthalmological Society.—Third Annual Meeting. Boston, June, 1866.

This Society, whose proceedings were reported in our columns, has published the papers read at the last annual meeting, in a handsome pamphlet of 46 pages. The papers are generally interesting and instructive. In consideration of the verboseness of transactions of medical societies in general, we are hardly disposed to criticise this modest book on that score; yet, even here, in one or two instances, pruning would benefit the papers. They are on—1. Sudden Monocular Amaurosis, by *Dr. Sands*, a most carefully observed and well written case. 2. On the same subject, by *Dr. Allin;* the want of an immediate ophthalmoscopic examination deprives the case of the interest of the former one, leaving more for conjecture. The former was supposed to be due to hæmorrhage within the sheath of the optic nerve, and the loss of vision was permanent. In the latter the loss of vision was attributed to hæmorrhage producing pressure outside of the sheath, and sight was restored to a degree which ophthalmologists express by the fraction $\frac{20}{200}$, i. e. the patient could read letters at 20 feet which should be read at 30 feet. 3. *Dr. Dyer* reports a fracture of the lens of one eye, and of the anterior capsules of both eyes, from death by violent hanging (Probst's case). 4. *Dr. Hildreth*, a paper on Anæsthesia of the Cornea, without intra-ocular tension. 5. *Dr. Hay* on the refraction of a small oblique pencil of diverging rays by a glass plate with plane parallel surfaces. 6. *Dr. Derby* on the necessity of employing greater accuracy in ascertaining and expressing the degree of acuteness of vision. The author recommends the use of a steady flame, uniform in intensity of illuminating power, always at the same distance from the letters, and placed in a room from which daylight is excluded. With almost Teutonic minuteness, two and a half pages are given to the recommendation and explanation of this method. 7. *Dr. Agnew*, a method of operating for divergent squint. 8. *Dr. Noyes*, Amblyopia produced by osmic acid, i. e. by its fumes The eye returned to its normal condition after one day. 9. *Dr. Noyes*, 3 cases of sub-retinal effusions, puncture; two were improved. 10. *Dr. Jeffries*, on the Anatomy and Physiology of the Ciliary Muscle in Man. He shows that the circular fibres of Müller of the ciliary muscle in contracting only assist the meridional ones, and remarks that he follows others in supposing that the method of action of the muscle is by contracting on its origin and slackening up the suspensory ligament, allowing the lens to beeome more convex, thereby accommodating the refractive media of the eye to the divergent rays of light from near objects, and focussing them on the retina. Dr. Jeffries also quotes from *Meyer*, of Bremen, and *Henle*, to show that the ciliary muscle differs so much in animals from that in man as to be useless in attempting to adduce from them the mechanism of accommodation in man; a belief which the author had previously enunciated. 11. *Dr. Williams* (Boston), Suture of the Flap after Extraction of Cataract, which has already been fully described in the Record.

Altogether this is a work creditable to the new and vigorous Society.

Watson Abridged; A Synopsis of the Lectures on the Principles and Practice of Physic. Delivered at King's College, London, by Thomas Watson, M.D., Fellow of the Royal College of Physicians, etc. (Abridged from the last English Edition.) With a Concise but Complete Account of the Properties, Uses, Preparations, Doses, etc. Taken

from the U.S. Dispensatory of all the Medicines mentioned in these Lectures, and with other valuable additions by J. J. MEYLOR, A.M., M.D. Philadelphia: Published by the Author. 1867. Pp. 277.

THE volume on our table is really a very valuable help in an emergency: it is a faithful abridgment, and as such we commend it to the profession. Still, Dr. Watson, who has come to be regarded as the Goldsmith or the "gentle Elia" of medical literature, has been made to exchange many a grace of manner for the conciseness of Tacitus. This we somewhat regret, but deem unavoidable in a practical age. The work will be frequently referred to by its possessor, and with profit.

RESEARCHES UPON "SPURIOUS VACCINATION;" or, the Abnormal Phenomena accompanying and following Vaccination in the Confederate Army during the recent American Civil War, 1861–1865. By JOSEPH JONES, M.D., Professor of Physiology and Pathology in the Medical Department of the University of Nashville, Tenn. 8vo., pp. 132.

THIS monograph is perhaps the most exhaustive one that has been written in any language upon the subject, and is a credit not only to the author, but to American medicine. The treatment of the different questions connected with the influence of poor diet, skin diseases, and syphilis, in affecting the integrity of the virus, is both able and conclusive. No pains have been spared by our author to collect all the material which could have any bearing upon the points at issue; and the number of facts from which he makes his deductions are, to say the least, immense. We commend the pamphlet to the careful perusal of every general practitioner, with the assurance that they will be satisfied that our author has most skilfully and effectually performed a very onerous task.

INHALATIONS IN THE TREATMENT OF DISEASES OF THE RESPIRATORY PASSAGES, particularly as effected by the use of Atomized Fluids. By J. M. Da Costa, M.D., Physician to the Pennsylvania Hospital, Fellow of the College of Physicians, etc., etc., etc. Philada. J. B. Lippincott & Co., 1867. pp. 86.

THIS excellent monograph, got up by the publishers in superb style, well supplies a want felt by the profession. The merits and objections of the various instruments employed for the application of nebulized fluids are commented upon, and the literature of the subject presented in an agreeable manner. The conclusions of the author given in a previous number, renders an extended review unnecessary. The illustrations are excellent, and the work itself should be in the hands of every practitioner desirous of keeping up with the therapeutics of his profession.

ON THE ACTION OF MEDICINES IN THE SYSTEM. By FREDERICK WILLIAM HEADLAND, M.D., B.A., F.L.S., Fellow of the Royal College of Physicians, etc. Fifth American from the fourth London edition. Revised and enlarged. Philadelphia: Lindsay & Blakiston. 1867. 8vo., pp. 428.

WHEN a work has reached its fifth American and fourth London edition, it hardly stands in need of any special commendation. The reputation of the author is so well established as a philosophical thinker, an ardent worker, and a reliable, conscientious, and practical teacher, that his work will always find a place upon the table of the studious practitioner, and the principles which are therein laid down be accepted and respected by every one who wishes for the advancement of the much neglected science of Therapeutics. We cannot resist the temptation of commending this valuable work to the serious study of that class, particularly whose ideas of the treatment of disease are narrowed down to tonics and stimulants.

PRACTICAL DISSECTIONS. By RICHARD M. HODGES, M.D., formerly Demonstrator of Anatomy in the Medical Department of Harvard University. Second Edition, thoroughly revised. Philadelphia: H. C. Lea. 1867. 12mo. pp. 271.

THE work before us fulfils its intention of being a practical guide-book for the student of anatomy in the ordinary prosecution of his studies in the dissecting-room. The author gives evidence upon every page of his fitness for the task, and shows that appreciation of the actual wants of the young dissector which nothing save that of demonstrator could have given him. The divisions of the work are most admirable, and the plan of describing the several parts which are conjointly exposed in a given dissection, is of obvious utility; while the restriction of the demonstrations to such appearances as are only to be expected after an ordinary dissection forms a very interesting feature of the work, and will tend not a little to give that encouragement to a beginner which he so much needs. It is very concisely written, and is of a very convenient size.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

STATED MEETING, APRIL 17, 1867.

DR. ALFRED C. POST, President, in the Chair.

A MECHANICAL APPLIANCE FOR CLEFT PALATE.

DR. KINGSLEY, of the College of Dentistry, by courtesy of the Academy, exhibited a patient to whom was adapted an appliance for cleft palate. He stated, that, according to his experience, the size of fissure bore no relation whatever to the distinctness of articulation. He said that the patient before the Academy had the largest fissure uncomplicated by hare-lip he had seen.

MEDICAL EVIDENCE.

DR. ORDRONAUX read a practical paper upon the subject above designated, in which he passed in review the various difficulties besetting the medical man upon the witness-stand. He said that most suits for malpractice had their origin in "envy, hatred, and all uncharitableness," and that medical witnesses often were unsuccessful from a deficient linguistic power and a want of self-reliance. To say nothing of a full and abundant knowledge of the subject, others failed to render themselves intelligible to a jury, owing to a too liberal use of technical terms. Again, lawyers are apt to insist on reasons when none can be given; Dr. Winslow, of London, who was perhaps oftener summoned to court than any expert in England, was not unfrequently put in this position.

Lawyers also exhibit a want of precision and candor in putting questions—neither counsel nor witness understand each other—so that the testimony does not become what was intended, an unbroken chain of cumulative evidence. But on the other hand, experts should bear in mind that they are not partisans, but that, as their duty is to throw light, they are advisers and counsellors of the court itself. Being thus unprejudiced, their opinions can never be unilateral in character.

Witnesses in these cases do not testify on matters of knowledge, but of belief, as grounded upon the generalization of facts. As to conflicts among experts regarding special methods of therapeutics, the court can make no distinction, but admits witnesses as experts in their own calling, and leaves the decision regarding credibility to the jury. The court thus takes refuge under its neutrality.

Experts are not allowed to state their views in matters affecting character, or their opinions regarding conduct; to illustrate, the court has stopped a witness who averred that a brother practitioner had acted dishonorably, such a course being deemed extra-professional.

It is not necessary that the "*skilled witness*" should be engaged constantly in practice, the presumption being, that, after having duly collated authorities, he represents the leading opinion. He cannot read from books in court, because the opinion sought is his own; besides, professional books deal only in universal propositions, while every case has a complexion of its own.

Notes may be used to refresh the memory touching facts, and it is not essential that the script be in his own hand, or made on the instant; if he speaks of them *knowingly*, his testimony loses nothing in value.

The doctor dwelt somewhat upon the confessions of patients, holding that the only exception to their being privileged communications, exempt from repetition in court, was in cases where facts, detrimental to public policy, might be concealed. As precedent, he cited a case where the physician was compelled to give evidence that a prescription was sought from him for the criminal purpose of abortion.

Around cases of insanity there clustered many difficulties—other experts are pitted against him, and when called upon to prove that a party is or is not insane, he cannot be expected to offer what is satisfactory to all. Some questions being incapable of explanation cannot be answered categorically, *i.e.* by *yes* or *no*.

Experts should carefully avoid the common error of forming an opinion upon isolated facts, and should not lose sight of the element of contingency. Above all he should not be entrapped into branching off from his subject, but always keep this fact prominently before him, that fallacies are feints to make an antagonist uncover. Such questions as "*Are or are not wounds of the head mortal?*" "*Is the mind a unit or composite in its organization?*" do not admit of a categorical answer. Upon the subject of insanity diverse opinions will always prevail, according as the cause may be regarded as psychological or somatic.

Experts may differ about the degree, but not about the fact. Nor can an opinion be based upon the degree of excitability.

Dr. Anderson then read the bill pending before the Legislature, which provides for the suppression of the circulation of publications, circulars, etc., suggesting means to produce criminal abortions. The penalty attached is one year's imprisonment in the county jail, and a fine of $1000.

The Academy then adjourned.

Stated Meeting, May 1, 1867.

Dr. Alfred C. Post, President, in the Chair.

A NEW METHOD OF RESUSCITATION FROM HYPERANÆSTHESIA BY CHLOROFORM.

Dr. Worster related a case in which chloroform had been administered to a patient, by a party whom he regarded as competent, as a preparatory step to an operation, by himself, for the relief of hæmorrhoids. Suddenly the patient had stertorous breathing, became pulseless, and exhibited all the symptoms of a speedy dissolution, but by the simple expedient of reversing his position, and inclining his body to an angle of forty-five degrees, he was fully restored.

Dr. Chamberlain said that his experience coincided with observations of other practitioners, that in all operations about the anus, it was exceedingly difficult to bring patients under the influence of an anæsthetic.

Dr. Richards suggested ether spray as a safeguard against accident in all operations of this kind.

EVERSION OF THE LID IN AFFECTIONS OF THE EYE IS ALWAYS IMPORTANT.

Dr. Garrish gave the details of a case in which a young girl, after having been treated at her home in the country for what was termed "a cold in the eye," came to him with lids so tumefied that it was almost impossible to get at the true condition of the globe, which was then just on the point of evacuating its contents. Soon after this, along with the other discharges, appeared a small folded piece of paper, which, in imitation of her fellow pupils, the little patient had inserted beneath the upper eyelid. He cited the case merely to show the importance of always everting the lid in all affections of the eye; it was a point not to be too strongly insisted upon.

A CASE OF REDUCED SUBGLENOID DISLOCATION OF THE HUMERUS.

Dr. Post gave the particulars of a case of subglenoid dislocation of the *os-brachii*, where etherization, combined with Dr. Nathan R. Smith's method of counter-extension from the opposite wrist, had failed, but by applying the heel to the axilla in the usual way, reduction had been effected with comparative ease. His success, and this he had before observed, was to be attributed to the fatigue of the muscles, induced by the previous manipulation.

PREGNANCY IN A DOUBLE UTERUS DETECTED DURING LIFE.

Dr. Peaslee recited the case of a lady who had travelled some 400 miles for an opinion regarding the nature of a tumor. She was the mother of five children, and insisted that she felt the motions of a fœtus, but the tumor, which was sensitive on pressure, and had a peculiar nodular feeling, was confined entirely to the right of the umbilicus. After a careful examination, the question arose in his mind, whether or not it was a case of extra-uterine pregnancy, since the head was well up in the iliac region and to the right side of the vagina. But having detected that the tumor was separated from his finger only by a *membrane*, and having discovered higher up the edge of a thin septum, he concluded that the right half of the uterus had received the ovum, and that the left half had not been impregnated; or, in other words, that the patient had a double uterus. It was not long before the husband summoned him to the bedside of the patient, with the announcement that the patient appeared to be in labor, which proved to be the fact. The fœtus was six months old. He thought that this condition of things was rarely detected during life.

TWO CASES OF VOCAL POLYPI ASSOCIATED WITH POLYPI OF TONSIL OF CORRESPONDING SIDE.

Dr. Richards gave two instances where a polypus, situate upon one of the vocal chords, was associated with a fibrous polypus of the right tonsil. This was not frequently suspected during life, and he mentioned it to show that there might be some inexplicable connexion between the two conditions.

The Academy then adjourned.

Ready Made Authors and Doctors.—There is a "Literary Bureau and Agency" in London, at which, according to a communication received by a respectable surgeon from its conductor, "original well written medical MSS., and a medical diploma, M. D., New York," can be obtained for a reasonable sum. What a profitable business such a bureau would do on our side of the water!

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, MARCH 13, 1867.

DR. H. B. SANDS, President, in the Chair.

DR. POST exhibited specimens of ossification of the upper part of the aorta and radial arteries, removed from a dissecting-room subject, aged about sixty years.

He also presented some calcareous concretions taken from the meibomian glands of a patient who called to his office complaining of some foreign substance in the eye. An examination of the lid disclosed the presence of some small calculi, which were easily turned out with the point of a pin.

HYPERTROPHY OF SPLEEN.

DR. ALLIN exhibited an enlarged spleen, weighing seven pounds and eleven ounces, which he removed from the body of a man who died of apoplexy, after having suffered from dyspepsia for the last seventeen or eighteen months, and from occasional attacks of dyspnœa for four months. The tumor was recognised several months before death, and was supposed to be due to malignant disease. The gross appearances of the organ were perfectly normal; no microscopic examination of the tissue had been made.

DR. ROGERS alluded to the case of the late Dr. Tuttle, whose spleen weighed about seven pounds.

DR. FINNELL, on behalf of Dr. W. Beach, Jr., presented a specimen of extra-uterine pregnancy. It was removed from the body of a German woman thirty-seven years of age. She menstruated regularly up to two or three months ago; three weeks ago a bloody discharge commenced, which continued for two weeks, at the end of which time, on Monday last, she was taken with violent cramps, which, although they relaxed a little during the following morning, finally terminated in her death on Tuesday evening. In conclusion, he remarked that the case would have been a proper one for the trial of the plan of arresting the attendant hæmorrhage proposed by Dr. Rogers.

On motion of DR. FLINT, a committee consisting of Drs. Draper, Smith, and Allin, was appointed to make a microscopical examination of the spleen presented by the latter gentleman, and report at the next meeting.

AMPUTATION OF ANKLE-JOINT, ETC.

DR. SANDS lastly presented a specimen of amputation at the ankle-joint accompanied with the following history:

While visiting the wards of the New York Hospital a few days ago, my attention was called by the house surgeon to a young man, æt. 21, who had requested that I should amputate his leg, on account of a disease of his right ankle which had troubled him more or less since childhood, and which had, for some months past, disabled him from going about. On examination I found the ankle somewhat swollen, with several fistulæ on its inner aspect leading down to carious bone. The ankle-joint appeared to be firmly anchylosed. From the length of time the disease had lasted, and from the depth and extent of denuded bone detected by the probe, I determined to put the patient under ether, and endeavor to amputate at the ankle-joint by breaking up the existing adhesions. Having made the usual incision, I succeeded, by employing considerable force, in separating the foot, together with a thin shell of bone from the articular surface of the tibia. The saw was then applied to remove the malleoli, and the wound brought together in the ordinary manner. Subsequent examination of the amputated foot showed: 1st, bony anchylosis at the ankle-joint; this, where it existed, was very firm, as evinced by the fracture which took place just above the level of the articulation, at the time of the operation. It did not extend, however, to the surfaces between the astragalus and malleoli, these being covered with the soft, gelatinous substance so commonly seen in disorganized joints. 2d, bony anchylosis between the astragalus and os calcis, complete, and involving both the posterior and anterior calcaneo-astragaloid articulations. A fact which seemed difficult to explain was the strict limitation of the morbid process to the parts just mentioned. As the members were aware, there were two pairs of articular surfaces between the astragalus and calcaneum. The posterior of these was provided with a separate synovial sac, while that of the anterior was continuous with the articulation between the astragalus and scaphoid. In the specimen it would be noticed, that the disease was strictly confined to the surfaces between the astragalus and calcaneum; the head of the astragalus, and the corresponding surface of the scaphoid bone being normal, and covered with healthy articular cartilage. Dr. Sands thought that the facts might be most easily explained by assuming the existence, in the case now related, of a distinct synovial sac for the articulation between the astragalus and scaphoid.

STATED MEETING, MARCH 27, 1867.

DR. H. B. SANDS, President, in the Chair.

SUB-PLEURAL EXTRAVASATION.

DR. FINNELL exhibited several specimens, the first of which were the lungs removed from a child three months old. The patient seemed well, when it was suddenly seized with a crying spell lasting for several hours, which was evidently due to internal pain, after which this dyspnœa appeared, and the child died after several hours, from suffocation.

The post-mortem examination gave no internal lesion to account for the pain, beyond the condition of the lungs, which showed extensive extravasations of blood underneath the pleura. There were no evidences of pulmonary apoplexy.

RUPTURE OF LEFT VENTRICLE.

The second specimen consisted of the heart and kidneys taken from the body of a man fifty-five years of age, who had been in ill health for two or three months preceding his death, during the most of which time he was obliged to keep his room. His principal complaint was severe pain and distress in the precordial region. His physician recognised some form of heart-disease, and advised him accordingly. He went out one evening with his daughter, and while passing through the street met some obstacle on the sidewalk which required a little exertion on his part to prevent a fall; soon after he expired.

The post-mortem disclosed rupture of the left ventricle, about its middle. The walls of the organ were as thick as normal, but were subject to extensive fatty degeneration. Both kidneys were found in the same condition.

FATTY PLACENTA.

The third specimen was a fatty placenta. The female from whom it was discharged had given birth to five living children, and was to all appearance in perfect health. The last labor was a perfectly natural one, but the child lived only three hours after birth. The placenta had very much the appearance as if it were sprinkled over with a handful of coarse salt, and at certain points the sensation communicated to the finger was similar to that which would be produced by calcareous degenerations.

ANEURISM OF AORTA.

The fourth specimen consisted of a heart in which an aneurism had burst just above the aortic valves, filling the pericardium with blood. The precise point of rupture into the sac could not, in the hasty examination made, be determined. The rent in the internal coat appeared as if made by a knife, and then the blood dissected its way for a considerable extent underneath the cellular coat.

The fifth specimen was removed from a man fifty-five years of age. He had been in ill health for two months before his death, with heart symptoms. The day previous he had complained more than usual of pains around the precordial region, accompanied with great distress. He gradually sank afterwards, and died. On post-mortem examination the pericardium was filled with clotted blood, and on looking down into the left ventricle, through the aorta, all traces of the semilunar valves had seemingly disappeared. Taken from the same subject was the lower end of the sternum with the eighth rib attached, showing a fracture of the latter bone, and which had become united by an overriding of the fragments.

Dr. Krackowizer discovered the aortic valves which were, on casual inspection, supposed to be absent, and found that they were nearly sufficient.

Dr. Markoe thought that blood in this case did not empty directly into the pericardium, but that it found its way there gradually. If it had escaped suddenly into the sac death would have been instantaneous, as the blood surrounding the heart would have prevented a dilatation of that organ.

THE EFFECTS OF ABORTION.

Dr. Finnell lastly exhibited a sixth specimen, consisting of the uterus and appendages of a victim of abortion. The woman was twenty-eight years of age, and died on Saturday, March 24. On the 22d of February last, finding herself between three and four months pregnant, she determined to have an abortion produced. She accordingly applied to an abortionist on Third Avenue for that purpose, and was operated upon by him about the 20th of March. No effect following, she had the operation repeated, but nothing came of it, and she applied to him a third time. A day or two after her last visit to the abortionist, symptoms of abortion showed themselves, and the fœtus was soon after expelled. From that time, until her death on the 24th, she suffered from symptoms which were of a pelvic character.

The autopsy was made with the assistance of Dr. W. Beach. On laying open the abdominal cavity there were no evidences of effusion in the peritoneum, but a large abscess was discovered in the right iliac region in the neighborhood of the broad ligament of the uterus. This abscess pressed upon the right iliac vein, which accounted for an œdema of the lower leg. On tracing the veins in the neighborhood of the abscess, they were found full of coagula, but no pus was discovered in them. The uterus was soft, larger than natural; the os was intensely congested, but there were no signs of recent abrasions. On the left side of the organ, in the neighborhood of the internal os, were two or three darkened spots resembling sloughy tissue, probably the results of previous attempts at abortion. They had evidently no direct connexion with the last illness of the patient. The site of the placenta was at the left and upper portion of the fundus, as shown by the characteristic roughened surface. In the right ovary two corpora lutea were found. The opinion given of the cause of death was intra-uterine phlebitis.

Dr. Garrish asked if there ever had been presented before to the Society a case of abortion, followed by death, in which no evidences of peritonitis existed.

Dr. Finnell was under the impression that several cases of the sort had been reported, and Dr. Krackowizer called to mind one in particular, presented by Dr. Voss.

ULCERATIVE DISEASE OF LARYNX, ETC.

Dr. Rogers presented the trachea and annexa removed from the body of a lady thirty-three years of age. He then gave the following history of the case:

She is said to have contracted a syphilis, some five or six years ago, which became constitutional, and among other manifestations presented that of ulcerative disease of the larynx, glottis, and epiglottis. About two years ago she began to fail in voice, which was gradually reduced in a short time to a mere whisper. About a year ago dyspnœa became quite urgent, she being subject to paroxysms of greater or less severity at different times. About that time, as I understand, Dr. Simrock saw the case, and made a laryngoscopic examination; his diagnosis was ulcerative disease of the larynx, involving the glottis, adhesion of the epiglottis to the upper rim of the larynx, and a perforation of the epiglottis, through which all the air that was inhaled entered the trachea. Not many months after this Dr. Parker was called to the patient, and during a fit of dyspnœa, from which she was then suffering, introduced a tracheal tube, which the patient wore until death. Total loss of voice soon followed, and within two months complete occlusion of the air-passage above the tracheal tube. She was seen on one or two occasions, subsequently, by Dr. Simrock, who still adhered to the diagnosis previously made, and concluded further, that in addition, there was an occlusion more or less complete of the left bronchus. She, in the meantime, suffered from bronchial symptoms, of more or less severity, and for different periods. Yesterday she suffered one of the ordinary paroxysms, and her physician, Dr. Lafayette Ranney, was called to her. He did not look upon the occurrence as anything unusual, and soon left the patient. In two hours after she expired, unaccountably.

The post-mortem examination was made at the request of a brother of the deceased. It is found, first, that a great part of the epiglottis has been destroyed by disease, that the remnant is adherent to the upper rim of the larynx, as Dr. Simrock had diagnosticated, but that the opening seen by the laryngoscope was a common one into the posterior part of the larynx, and into the œsophagus, resulting from adhesions of the apex of the pharynx to the fragment of the epiglottis. During the healing process this common opening had so narrowed down, that when dilated to the utmost, it did not seem to be more than three-eighths of an inch in diameter, and yet it is said that the patient ate solid food like any one else. Passing the probe down through this opening, it is seen to emerge into the œsophagus. Immediately after leaving the epiglottis you may observe the point of the probe fall into a cavity, which, looking at it from behind, gives you an appearance of an ordinary glottis, but further down you find that it is a cul-de-sac, the larynx being occluded at its lower border, and dissecting from below you come in contact with that occlusion, which is cartilaginous in character, at the lower rim of the thyroid cartilage. By passing a probe through the opening, which I have made at the upper edge of the larynx, it is seen to pass out just above this material which occludes the passage. The tube has been worn for a period of nearly nine months.

Following the trachea down, we have evidences of very extensive ulceration. In confirmation of the

diagnosis made in regard to occlusion of the left bronchus, a dark-looking substance will be seen in the trachea, just near the bifurcation. The cause of death was found to be occlusion of the tube with a large mass of very tenacious mucus.

Dr. Krackowizer remarked, that the occlusion of the left bronchus was due to a perforating ulcer of the trachea near the bifurcation, which admitted the protrusion of one of the lymphatic glands, situated normally upon the outside of the tube.

(To be continued.)

Correspondence.

MEDICAL MATTERS IN PHILADELPHIA.

To the Editor of the Medical Record.

Sir—Items of general interest among the profession in this city are scarce at present. The latest movement has been the formation of the Philadelphia Union Medical Association, an organization started by some of the general practitioners in the northern section of the city, for the object of promoting professional improvement among themselves, a better acquaintance with each other, and of protecting their pecuniary interests. Some fifty gentlemen joined the organization, appointed a committee to qualify each other, and the rest joining, as original members, and adopted a Constitution and By-laws, and the fee-bill of the College of Physicians.

Medical organizations are not as numerous, nor as attractive in this city as in New York; why, it would be hard to tell. Some of the societies have a great many members, who rarely think of attending their meetings, whether for discussion or business, and many such inattentive members occupy prominent positions, and could add much to the literary interests of the organizations they neglect. Then there are a great number of practitioners of good repute and extensive practice, who are not members of any medical organization at all. Those few who take an active interest in medical societies are gradually endeavoring to imbue the profession with the idea that it should be considered a necessary evidence of good professional standing to be connected with at least one society of the kind; and an effort will be made, if possible, to induce every practitioner to join the County Medical Society, so as to make it the chief representative body, in connexion with the scheme of State Societies and the American Medical Association.

There is very much needed in the city a sort of a Journal Association, somewhat similar to that in New York; and an ineffectual effort was made some years ago to create a library of current medical literature in connexion with the County Medical Society. There are several book-clubs, private organizations, consisting of from twelve to thirty gentlemen, who club in this manner to subscribe to certain journals, or to purchase certain monographs, which they receive in a certain succession. But in this manner a journal is sometimes several months old before it has gone the rounds, and the object should be for all to have early access to it. This can be accomplished only by the establishment of a reading-room where the journals shall be kept open to the inspection of members, but from which they should not be taken until the lapse of a certain period after their date of publication. It is part of the design of the new medical organization to establish a reading-room of this kind, with which view efforts will be made to secure a list of members sufficiently large to meet the necessary expense.

The summer sessions at the College are in full operation, and attended better, if anything, than last year. The practical course at the Jefferson Medical College is a complete success, and many of the students are gaining more actual insight into the details of their profession than they did in the winter, when so many and so varied a variety of subjects were presented en masse to their crude understandings; and they will be able to enter upon their ensuing winter course with such preparation as will enable them to appreciate it.

The action of the Convention of Medical Teachers recently held in Cincinnati, appears to give general satisfaction to the profession, and to most of such as are engaged in assisting students with their studies; that is, the class of gentlemen engaged in private tutorship and quizzing; but the concurrence of the colleges, as a body, is considered extremely doubtful; and indeed it is much to be doubted whether any innovation at all will be permitted to interfere with the present incomplete method which, much as it might have been all-efficient even thirty years ago, is markedly inefficient at the present day, though many good doctors are turned out in spite of the system. The probabilities are, that unless coerced by the simultaneous action of other colleges in adopting a gradation in tuition the present system of instruction will continue in Philadelphia for some years to come, outside influence to the contrary notwithsianding.

Dr. R. J. Levis, in connexion with his course on ophthalmic and aural surgery, at Jefferson Medical College, has established an ophthalmic clinic which has been very instructive. There presented himself recently, at this clinic, a German, N. H., æt. thirty, with an enormous elephantiasis, or hypertrophy of integument of the left side of forehead, including the brow and upper eyelid, with lobed fibro-cellular outgrowths. The color of the skin is normal, but the weight of the tumor has dragged the upper eyelid down over the lower one and beyond it, clear down to the ala of the nose, by the side of which it lies, everted.

This patient was delivered with the forceps, and at birth was noticed to have upon his forehead a small lump the size of a pea, which continued to grow, until at the age of fourteen the eye became obscured; since which time it has grown very slowly. On forcibly elevating the eyelid, the eye was observed to be cataractous, with no perception of light. The patient suffers from photophobia with the other eye, and his intellect is somewhat obtuse.

Prof. Gross recently showed his class Maggie T——, æt. fifteen, from whom, at nine years of age, he removed the left lower limb at the hip-joint, on account of deformity and incurable disease, the result of a very bad scald. The patient at the time was very much prostrated; recovery was apparently hopeless, and at the consultation, two distinguished surgeons of this city expressed themselves averse to the operation, which was, however, performed, as affording the only chance of relief; and to the surprise of all concerned, the patient got well without a single untoward symptom, though she was so much emaciated at the time that compression of the aorta was easily effected through the abdominal parietes.

The annual meeting of the Medical Society of the State of Pennsylvania will take place within a fortnight, and considerable interest is felt as to what will be the action with regard to the status of female physicians, or "women doctors," as they are now being called, in consequence of the recent change of name of the Female Medical College of this city, to that of Women's Medical College, in order, it has been maliciously said, to leave no doubt as to the order in the animal scale of

those to be educated there, inasmuch as the word female was not sufficiently distinctive.

Yours truly,

C. J.

Philadelphia, June 1, 1867.

A REVIEW OF A REVIEWER.

LETTER FROM DR. H. G. DAVIS.

To the Editor of the Medical Record.

Sir—It is with reluctance that I ask a place in your columns to correct some mistakes that were published in another journal, the editors of which are unwilling to admit corrections. The statements I make are not limited in their influence to myself, for I trust that, as a profession, we entertain a feeling of national pride, and a desire, not only to do all within our power for its advancement, but to maintain our claims for whatever we may accomplish before the world.

The March number of the *New York Medical Journal* contains an extended review of my work, entitled "Conservative Surgery." The reviewer, in some instances, unfortunately has mistaken words for ideas, quoting from other authors words similar to those employed by me in Conservative Surgery, and representing said language as expressing my ideas, or as defining the processes mentioned in my work, when, in fact, they are entirely dissimilar, not possessing the least *resemblance*.

The reviewer says: "In the first chapter (on fractures) Dr. Davis writes: 'This principle of treating fractures by simple, continued, elastic extension, was urged by us upon the profession in the early part of the year 1856, etc.'" He then inquires: "What, may be asked, was the principle generally recognised by the profession who have used the straight splints of Dessault and Boyer, and their several modifications, with extension and counter-extension?" This inquiry can be the best answered by describing the mechanical appliances used by these gentlemen for effecting extension and counter-extension. In these splints the *extending force is applied through a screw*, or its equivalent; this screw is turned until the parts are as tense as the surgeon desires. This, be it remembered, is done while the muscles are contracted, and it fails to weary and tire them by continuing to act, but remains unchanged, without pulling or extending beyond the point where the limb was when the surgeon ceased turning the screw, and thus it must remain, for all that the fixtures themselves can do to change it. There is, then, absolutely no extension when the surgeon ceases turning the screw. Theoretically, the limb simply remains fixed at the length it was left by the surgeon, but in fact, it is constantly losing, as the appliances always will yield, more or less. Now, if the screw is not turned, there will necessarily result a loss of the distance first gained, or of an amount of extension equal to the first amount. It requires no argument to prove that the screw or its equivalent *cannot* of itself effect a continuous pulling or extension; it is *only* while the screw is being turned that extension is made; consequently, while the screw remains unchanged, the limb is simply fixed, as though it were nailed to the splint. The result is not changed when the screw gives place to an equivalent in the form of a twisted rope, as used by Dr. Neil, of Philadelphia. This surgeon did not aim to keep up a continuous pulling; he substituted the rope as a cheaper and more simple equivalent for the screw.

Although Prof. Nathan Smith, M.D., of New Haven, Conn., employed the cord, pulley, and weight, yet his dependence in treating a fracture was upon the inclined plane. Prof. Smith says: "In most instances in which the limb has been thus dressed (on an inclined plane), almost every source of irritation being avoided, and the attitude natural and easy to the muscles, *I have not found it necessary to use permanent extension.*"

We were not cognizant of this use of the cord and pulley by Dr. Smith until recently; had we been, it would not have detracted from our claim for having been the first to recommend "*simple, continued, elastic extension*" as the *only means necessary for the treatment of fracture in general*—extension, be it understood, *without even co-aptating splints.* The extension we use differs from the screw and its equivalents, in that it constantly acts; it never ceases pulling. It is this ceaseless, unremitting extension that wearies the contracting muscles, overcoming their resistance, and thereby permits the fractured bones to come into their natural position.

If the reviewer cannot appreciate the difference between extension (as it is termed) by the screw and its equivalents, and continued elastic extension, as here explained, we must ask him to perform both kinds by his own hands. On one he will pull or make extension only until his extension can be secured and fixed by this screw; in the latter, there being no screw to secure the extension already made, he must remain at his post, pulling or extending unremittingly.

The reviewer becomes quite facetious over a new mode, recommended by us, for overcoming muscular contraction in fractures for the patella; and some of the processes, where application for this purpose cannot be made to the parts fractured.

He stated that we applied, in a fan-shape, adhesive plasters *over the bellies of the muscles to be overcome*, and then made continued extension from their united inferior ends, by means of a cord, pulley, and weight. The manner of applying the adhesive straps we illustrated by several fine cuts. That this mode does not differ from all other modes of treating these fractures, requires and demands something more tangible than ridicule to prove to the contrary, particularly as the reviewer acknowledges it "to be a good one."

We should have thought the character of the sentence against which he enters his protest would have suggested to him that some qualifying word (apparently, for instance) had been omitted by the printer. We will add, for the information of the reviewer, that the patella, mentioned in our work, as treated upon this plan, yet remains firmly united after a period of fifteen months, which we think is quite unusual, to say the least, for one separated two and a half inches at the time of its fracture.

We come now to the reviewer's remarks upon our claims to having introduced some novel views of the pathology and treatment of diseases of the joints. The reviewer quotes what he designates as our "claims as distinctly formularized." The sentence he quotes is, however, simply a statement of what first arrested our attention, and led us to the investigation of the mechanical causes operating injuriously in joint diseases, and *not the discoveries themselves.* There is perhaps some excuse for this mistake, as the word discovery is used in the sentence in the sense of first noticed.

The claim, as distinctly stated by us, can be found on page 206 of Conservative Surgery, and is as follows: "We consider it fully established, *that when disease about a joint renders the movement of that joint painful, it is always liable to be destroyed by uninterrupted pressure effected through the contraction of muscles passing over it. They do this by preventing the parts pressed upon from receiving nourishment, in the same way as a bedsore is produced.* This view was first brought to the notice of the profession in a paper read before the New York

Academy of Medicine in 1860." On page 210, there is a similar, but more comprehensive statement.

We consider this an important fact in the pathology of joint diseases, and as distinctly stated, notwithstanding the reviewer's assertion, "That they are not mentioned in the work."

As to pressure upon diseased joints, the reviewer's quotations from Beale, Ford, and others, apply *only and exclusively to pressure from the weight of the body*, and *not to that effected* by the contraction of *the muscles passing over the joint.*

In his quotation from Ford, he (Ford) expressly says, in reference to morbus coxarius: "Nothing can be clearer than that patients must feel ease and advantage from every expedient to prevent *the weight of the body*, in any degree whatever, from pressing on the joint." But Ford goes further, and upon the next page says, "and that this shortening of the limb *does not depend* upon spasm and *contraction of the muscles.*" Here he expressly denies what the reviewer by implication asserts.

The reviewer quotes Beale as saying in reference to Delpech's apparatus: "Any benefit which may result from such an apparatus must be derived from the power of extension in overcoming the contraction of muscles." Is Beale speaking of the contraction of muscles in diseased joints? By no means; he is speaking of lateral curvature of the spine. In no instance does he speak of pressure as being effected in a joint through contraction of the muscles passing over said joint. All the quotations from authors made by the reviewer are not applicable, and do not in the most remote degree invalidate our claims to the discovery that the contraction of the muscles passing over a joint, holding it motionless, would destroy it by preventing the nutrition of the parts pressed upon, in the same way that a bed-sore is produced by pressure.

Even Sir Benjamin Brodie, although he used the cord, pulley, and weight, did not employ them as a remedial measure, neither did he recognise in any instance that the contraction of the muscles was a constantly acting force to destroy the joint. We have stated this case fully, and, as we conceive, fairly, in our work.

Drs. Harris and March both treated morbus coxarius by fixing the limb by the screw, seeking only rest to the joint, and anchylosis as the best result.

This certainly does not look like an effort to effect an entire separation of the head of the femur from the acetabulum, and to prevent all pressure from whatever cause during the whole period of treatment.

Here we leave the subject, with a consciousness of having endeavored to set the professional public right in regard to the truths we have advanced, with a firm conviction that the principles advocated in CONSERVATIVE SURGERY are destined to occupy an important place in the progress of things—not only in this, but in all countries where science and art are held in estimation.

Truly yours, H. G. DAVIS.

New York, May 15, 1867.

CHOLERA AND QUARANTINE.—We are requested to state that it was not the intention of Prof. C. A. Lee, in his resolutions upon cholera and quarantine offered at the late meeting of the American Medical Association, to express the opinion that all quarantine measures at our ports are useless in preventing the introduction of cholera into our country; for the disease had been kept confined to the lower bay of New York more than six months by such quarantine as then existed; but that, having once gained a foothold, no means short of non-intercourse could prevent its spread to other places.

THE ARMY MEDICAL BUREAU, AND THE AMERICAN MEDICAL ASSOCIATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—I am happy to learn officially that the unequal report of that part of the proceedings of the American Medical Association, relating to the resolutions on the Army Medical Bureau, was simply the result of unavoidable accidents. As, apart from any claim of equal justice, the action of the Association is an additional and special reason why the resolutions and the reasons then given for offering them, should be fairly presented and clearly understood, I respectfully request that the accompanying communication, with the original synopsis of remarks furnished previously by request, be published in the next number of your Journal.

"DR. BENJAMIN HOWARD, of New York, offered the following preamble and resolutions:

"'*Whereas*, There has been issued, and still remains in force, an official order from the Surgeon-General of the United States Army, prohibiting the communication of any medical or surgical information by any medical officer of the United States Army, to any person whatsoever, without special permission from the Medical Bureau, at Washington—thus appropriating, as far as the official power of the Surgeon-General can compass it, all the valuable experience and statistics of all medical men who have served in the various departments of the United States Army, to the exclusive use of the Medical Bureau. And,

"'*Whereas*, Under such arbitrary control, an official report has already been made, tending to create incorrect impressions, on scientific questions of great practical importance to the profession and to society. And,

"'*Whereas*, It is important to the reputation of all medical men who served during the war, that they have the opportunity of correcting such erroneous impressions by an examination of the original records. Therefore, be it

"'*Resolved*, That it is the opinion of this Association that the monopoly now exercised by the Medical Bureau over the medical and surgical records of the war, is contrary to the genius and catholic spirit of our profession, and obstructive to the highest interests of science and humanity.

"'*Resolved*, That the Secretary of War, or other proper authorities, be requested to direct that the original records of the Medical and Surgical History of the War be rendered accessible on certain regular days of each month, for purposes of scientific investigation to all medical men who have served as such in the army of the United States.'"

"In supporting the above resolutions, Dr. Howard stated that they were presented in the special interest of many members of the Association, and those not the least honorable, either on account of professional achievement or patriotic devotion. They contemplated alike the benefit of the profession, and of humanity throughout the world, no less than the greatest ultimate efficiency of the Statistical Department of the Medical Bureau. Many reasons were then stated at length why medical men who had served in the army should be allowed access to the records, at least of their own recent cases, of which the following is a synopsis:

"As the publication of the official reports is subject to political contingencies, such publication may be indefinitely postponed, or the project become totally abandoned.

"Meanwhile, a vast amount of unrecorded experience complementary to data in the Medical Bureau is being forgotten and lost. For though these together would furnish complete and reliable information, apart, each may be unreliable and worthless.

"Some members of this Association have been most carefully pursuing various and distinct lines of original investigation, and require each to study out the same cases in entirely different aspects. Should the promised

publication ever appear, no matter what its methods of classification, they cannot correspond to each of these original and separate lines of investigation, and therefore must, to at least the majority of such members, be simply worthless."

"Not a few of the best minds in the profession, having been officially prohibited any item of information, even so much as to whether certain late patients of theirs were dead or discharged, are kept at a steady halt in the midst of important researches, and valuable papers which otherwise might long ago have been in the possession of this Association, are consequently uncertain of ever reaching completion.

"Our professional brethren throughout Europe, apprehensive of instant and general war, are anxiously sending for the results of our recent and unprecedented experience; but those who otherwise would be best qualified to furnish to them and the future sufferers, the common charity they crave, are able only to echo the response of the Medical Bureau, and reply that it is contrary to the official order of the Surgeon-General to furnish any such information, until duly and officially published.

"The only plausible reason for this exclusive policy of the Bureau is, that it is necessary to the successful compilation of the Records. Two days of each month for opportunities of reference could not be a very serious source of delay. The Bureau would by such reference lose nothing; but it would thereby gain the superior advantages of comparison and correction from those best acquainted with the facts at the time they occurred, while it would obviate any tendency to that suspicion, which is inseparable from monopolies. In conclusion, our experiences during the late war, in so far as they may serve to ameliorate human sufferings, belong not exclusively to the Medical Bureau, to any State, or any country, but are the rightful property of the whole world."

These statements, noted nearly verbatim soon after they were made, interspersed with illustrative facts, constituted the more salient points of my remarks on that occasion. On referring to the printed report of my friend Dr. Woodward's speech, a single glance will discover that instead of being a reply *to*, it was a most successful diversion *from*, the principal questions presented, to a dutiful, but entirely gratuitous vindication of the "honesty," "ability," "humanity," and "conscientiousness" of the Surgeon-General, as if such were not the traditional qualities belonging essentially to that office.

In my friend Dr. Woodward's speech, I discover but two statements legitimately based upon the resolutions, or remarks preceding. The first, respecting the time of publication, was to the effect that within two months would be issued a catalogue of the museum, of about a thousand pages. To this my reply now is—The greater the volumes, the greater the delusion and the blunder, if, instead of furnishing just what is most needed in the manner alone in which it can be available, they be published as professional bulls, with such sacred and unalterable errors and misconstructions as may be found in the volume already issued.

The other, and the only one not anticipated in my first remarks, entitled "the still graver reason why the access asked cannot be granted," is, that it would be an additional obstacle to the adjustment of the claims of pensioners. In reply to this, by far the strongest and most pertinent objection raised, I would simply ask—suppose any one clerk in charge of any one set of books, under a particular officer, searches for a particular fact respecting a particular case, that fact being required by said officer for me—the original contributor; does that prevent or delay the adjustment of any pension any more than if the same, or a similar fact concerning the same case, be sought for by the same clerk, for the same officer, for insertion in the official catalogue of the Army Medical Museum? If the opportunity of a little additional reference, like that necessary to every item in the great compilation in progress, is totally objected to because it would delay the adjustment of pensions whose settlement is so imperatively "demanded by every consideration of humanity," by what rule of boasted "honesty," or "conscientiousness." has similar investigation been unremittingly pursued in each of the four thousand cases, the publication of which, in a volume of about one thousand pages, is promised us within the next two months? After careful attention to every attempt at justification, by the Medical Bureau and its agent, I am still waiting to discover the shadow of an honest reason why the medical men, who at every sacrifice of comfort, and frequently at imminent risk of their lives, operated upon and treated patients with most careful assiduity, and thus laid the foundation of the greater part of whatever is of any interest or value in the surgical and statistical department of the Bureau—why these men should be, as now they are, denied any and all information respecting any one of those cases which they have treated, and which they may have risked their lives to save.

B. HOWARD.

45 W. 31st st., New York.

Obituary.

JOBERT (DE LAMBALLE),

OF PARIS.

THE Paris *Gazette Médicale*, of May 4th, reports the recent decease of this eminent surgeon. His obsequies, which took place the Friday preceding at the church of the "Madeleine," were attended with great pomp, and an immense concourse of persons. Marshal Vaillant represented the presence of the Emperor. The Imperial Academy of the Sciences and the Academy of Medicine testified by the attendance of their respective presidents and members the high and honored position which Jobert occupied as a member of these scientific institutions. The Paris School of Medicine was represented by a deputation of professors and assistant professors in their robes, headed by the Dean of the Faculty. Several funeral discourses were pronounced over the corpse:—Dr. Conneau, first physician to the Emperor, spoke in the name of his Majesty; M. Gosselin in the name of the Paris School of Medicine; M. Legouest expressed the feelings of the Academy of Medicine; and M. Arnal those of the personal friends of Jobert. The sad misfortune which overtook this great and distinguished man before his death, is known to all. In the wreck of his intelligence were explained those eccentricities which frequently characterized his private life. He commenced his medical career in 1819, from an humble origin, with an imperfect education, and in extreme indigence; with an intellect brilliant and ardent, dominated by an inflexible will and fixedness of purpose in the pursuit of distinction, and the attainment of excellence in his profession, Jobert had many warm friends, and some bitter personal enemies. By his irresistible will and unremitting application, he attained to distinction, and the possession of a most ample fortune. As surgeon to the Emperor; member of the Imperial Academy of the Sciences; of the Academy of Medicine; member of the Institute of France; commander of the Legion of Honor; professor of the School of Medicine at Paris, Jobert was suffi-

ciently entitled to the mortuary pomp and splendor which commemorated the respect of the French nation, as evinced through its high dignitaries and scientific bodies. The application of his physiological researches to wounds of the intestines by the immediate contact of their serous surfaces, originating the extensively-adopted procedure called the suture by "invagination;" his important advances in the treatment of vesico-vaginal fistula by the method called that of "glissement," though far surpassed by the inventive genius of American surgery; his numerous publications, and his brilliant operative skill; these are distinctions which claim for Jobert the regard of all medical men.

Medical News and Items.

DR. DANIEL G. BRINTON, formerly Surgeon and Brevet Lieut.-Col. U. S. V., has become an associate with Dr. S. W. Butler, editor *Phila. Medical and Surgical Reporter*.

DR. MARTYN PAYNE, the venerable Professor of Materia Medica in the University Medical College, has retired from the active duties of his chair, after an acceptable service of twenty-five years, and is now Emeritus Professor. His successor, Dr. William H. Thompson, brings eminent qualifications to the position.

NATIONAL ASYLUM FOR DISABLED SOLDIERS. — The Board of Managers have decided to purchase the Ohio White Sulphur Springs property, near Columbus, Ohio, as the Central Asylum; Dr. C. M'Dermont being elected medical officer. From a Washington despatch to the newspapers we clip the following, which gives much useful information:

The Board of Managers of the National Asylum for Disabled Volunteers gives notice that it is now prepared to receive beneficiaries into the branches located near Augusta, Maine; Milwaukee, Wisconsin; or into the Central Asylum, near Columbus, Ohio. Volunteers are admitted upon application, by letter, to either of the managers, whereupon a blank application will be sent to the applicant, and, if duly qualified, transportation will be furnished him. The requirements are: First, any honorable discharge from the volunteers. Secondly, disability by wound received or sickness in the line of duty. If the applicant is unable to travel, or for other sufficient cause, relief will be furnished under direction of the manager to whom application is made. Overseers of all alms-houses and charity hospitals, having disabled soldiers subsisting upon private beneficence, are respectfully urged to report such cases to either of the managers, as it is not fit that meritorious disabled soldiers of the nation should be supported by private or public charity. Soldiers are especially informed that the asylums are neither hospitals nor alms-houses, but houses where subsistence, care, education, religious instruction, and employment are provided for disabled soldiers by the Congress of the United States, to be paid for by forfeitures and fines of deserters from the army. The provision is not a charity. It is a contribution by bounty-jumpers and bad soldiers to the brave and deserving, and is their right. Soldiers having a wife, child, or parents dependent upon them, are not required to give up their pensions upon coming to the asylum. Other soldiers are required to assign their pensions to the asylum, in special cases only, to be determined by the Board. Suitable compensation will be given for profitable labor in the asylums. Good behavior will insure the kindest treatment. Wives and children will not be cared for at the asylum until after a soldier has shown his ability to aid himself and them in part by his labor and steadiness, so that taking his family in charge will not increase his expenses to the asylum above the cost of other helpless beneficiaries, in which cases provision will hereafter be made.—*Cinc. Lancet and Observer.*

NEW LUNATIC ASYLUM IN OHIO.—An act has passed the Legislature of Ohio to establish a lunatic asylum in the south-eastern part of the State. No location is as yet selected.

ASYLUM FOR AGED INDIGENT FEMALES.—Dr. F. A. Burrall has been appointed attending physician to this Institution, *vice* Dr. James S. Cooper, deceased.

THE QUARTERLY JOURNAL OF PSYCHOLOGICAL MEDICINE AND MEDICAL JURISPRUDENCE, is to be the title of a new medical Periodical to be issued on the 1st of July next.

The contents will embrace: 1. Original articles on the Physiology and Pathology of the Mind and Nervous System, and on questions of Medical Jurisprudence. 2. Selections and Translations of Memoirs from Foreign Journals. 3. Reviews and Bibliographical Notices. 4. Chronicle of the Physiology and Pathology of the Mind and Nervous System and of Medical Jurisprudence. It will be edited by WILLIAM A. HAMMOND, M.D., of this city.

CLIMATE AND DISEASES OF UTAH.—The eruptive fevers, measles, scarlatina, and small-pox prevail more or less throughout Salt Lake valley, but in general, epidemics are not common. The healthfulness of the climate, and the manner of life of the Mormons, are not favorable to the production of disease. Physicians do not flourish in Salt Lake City. But two were living there at the time I left the valley, and both were in a state of destitution. The Mormon bishops cure all diseases by the imposition of hands, or themselves administer the remedies; they will not permit the services of a physician, and do not scruple to denounce the use of carnal means to promote recovery. The faith of the ignorant Mormon people should not surprise us, since we know that many diseases are self-limited, and hence the efforts of the bishops and elders seem in most cases to be successful. The Mormon belief in the efficacy of prayer is quite as sensible as the blind confidence of many intelligent people in the dicta of Hahnemann. The absence of morbific causes, and the healthfulness of the climate, render the valley of the Great Salt Lake especially desirable as a residence for invalids. There is probably no part of this country more favorable for consumptive invalids.—*Bartholow.* (*Cin. Lancet and Observer*).

PROVISIONS FOR THE PHYSICAL AND MEDICAL WANTS OF THE METROPOLIS in the tax levy adopted by the late State Legislature. Among the apportionments of

the tax levy we notice the following: City Dispensaries, $11,000; Donation to St. Francis Hospital, $5,000; to House of Good Shepherd, $5,000; Women's Medical College and Children's Hospital, $5,000; Donations, Five Points House of Industry, for a Working Women's Home (provided the same sum is raised by private subscription within 1867), $20,000; donations, Institution of Mercy, Houston street (on condition an equal sum be raised by private donation in 1867), $30,000; donations to the blind, distributed by Commissioners of Charities, $20,000; Northwestern Dispensary (when the same sum is raised from private sources) for new building, $15,000; for constructing Inebriate Asylum, $100,000.

A Substitute for the Stomach-Pump.—Dr. R. W. Park, of Mobile, Ala. (*Med. and Surg. Reporter*), calls the attention of the profession to a ready substitute for a stomach-pump. The apparatus consists of a common Davidson's India rubber syringe and a large size gum elastic catheter attached to it. By introducing the catheter (or what is still better, a stomach-tube) into the stomach, and attaching it to one end of a Davidson's syringe, the stomach can be filled in a few seconds with water, and by reversing the syringe as quickly erupted.

Diet for the Infant.—The best of all diets for an infant who cannot have the breast, is one part of cream, two or three parts of water, according to the density of the cream, and enough sugar to make the mixture very sweet. The chemists who have analysed the milk produced by various animals, tell us that the fluid produced by the woman and the ass contain the smallest amount of curd, and that both are very saccharine; and experience tells us that the mixture recommended above, forms the nearest approach to the maternal fluid.—*Dr. Inman, (London Medical Mirror).*

An Item in the History of the Removal of Ovarian Cysts.—"A woman, betwixt twenty and thirty years of age, had been tapped twice for an ascites, and a large quantity of water taken away at each time; but after the last operation the puncture did not heal, and in a little time, a substance they did not understand protruding, I was desired to see her. It was evidently a part of a cyst, and, as it had already dilated the sore, I persuaded her to let it alone till the opening became larger, in hope of a better opportunity of affording relief. Accordingly, in ten days or a fortnight the protrusion was much larger, and by the help of a dry cloth a cyst that would contain five or six gallons of water was gradually extracted. More than a quart of matter immediately followed, and more was daily discharged for some time, yet the woman recovered without further trouble than keeping the parts clean, and afterwards bore several children."

We have extracted the above from that interesting and valuable work written by Thos. Kirkland, entitled, "An Inquiry into the Present State of Medical Surgery," published in London in 1786, vol. 2, p. 195. We give it as an interesting item in the history of the removal of ovarian cysts, and we may further add that in the appendix to the same volume, p. 570, Mr. Kirkland makes the following proposition:

"We have given an instance, p. 195, where a cyst being taken away cured an ascites; and seeing medicines do not avail in encysted dropsies of the abdomen, is it not worth our while to consider whether, when they are unconnected with the adjacent parts, after taking away the water, the patient might not sometimes be cured by enlarging the puncture, pressing the cysts forward, and draining it out?" He then proceeds to examine the difficulties in the way and the objections which may be brought against the operation, and thus concludes: "At present, I offer these hints to those who think the subject deserving attention, and time will probably determine the question."

Eighty years have passed since the above was published, and time has determined the question, and that, too, most emphatically in favor of Mr. Kirkland's proposition.—*Exchange.*

The Signs of Age.—But the aged are far more readily pulled down by medicine than the young. An aperient dose which will make a lad more lively than before, will give his father half a week of flatulency; and the blue-pill which was thought to clear the liver of the juvenile *bon-vivant* is sure to promote biliousness in the senile feaster. Those who in advanced years go to the druggist for a calomel purge to clear away the remains of some aldermanic feast, are those most apt to die suddenly of apoplexy, and that which has long been trusted as a valued friend, becomes at length the deadliest of enemies. But there is another point connected with advancing years which we must advert to, tender though the ground may be. There is a time in the life of a woman when Nature sets a limit to her power of reproduction. There are few like Sarah, who become mothers in old age. In man, however, there is no such limit. Abraham, we are told, had a family by Keturah after his first old wife was dead; and though the aged David could lie quietly by the lovely Abishag, at the age of eighty, or thereabouts, yet the story runs that "Old Parr" was arraigned at a still more advanced period of his life for having violated some young woman. A wide experience of the world tells that marriages occasionally are solemnized between aged men and young wives, and are sometimes followed by a family, whose paternity is undoubted. This being so, there is a general belief that men usually carry into years the powers they have in youth, and they consequently try to demonstrate year after year to themselves that no sign of age has yet fallen on them. I once heard, with the most profound disgust, an old colonel of seventy-five say, in a mixed company, that his fourth wife was as well treated as his first, and his tone and manner showed how proud he was of making the boast. A few months only elapsed ere he succumbed to an attack of fever, apparently mild.—*Thomas Inman, M.D. (London Medical Mirror).*

The City of Austin, Nevada, is six thousand feet above sea level, where the air is so thin that the least physical labor causes great shortness of breath, and the atmospheric pressure is so light that those of its four thousand inhabitants who find it necessary to wear artificial teeth experience extreme difficulty in keeping their sets in position.—*Sci. American.*

An Extinct Race.—One of the most remarkable races that ever inhabited the earth is now extinct. They were known as the Guanches, and were the aborigines of the Canary Islands. In the sixteenth century, pestilence, slavery, and the cruelty of the Spaniards succeeded in totally exterminating them. They are described as having been gigantic in stature, but of a singularly mild and gentle nature. Their food consisted of barley, wheat, and goat's milk, and their agriculture was of the rudest kind. They had a religion which taught them of a future state, of rewards and punishments after death, and of good and evil spirits. They regarded the volcano of Teneriffe as a punishment for the bad. The bodies of their dead were carefully embalmed and deposited in catacombs, which still continue to be an object of curiosity to those who visit the island. Their marriage rites were very solemn, and before engaging in them the brides were fattened on milk. At the present day, these strange people are totally extinct.—*Med. and Surg. Reporter.*

Original Communications.

OUR PRESENT EXACT KNOWLEDGE OF THE CAUSES OF CHOLERA.

READ BEFORE THE NEW YORK MEDICAL JOURNAL ASSOCIATION,

By M. HERZOG, M.D.,

OF NEW YORK.

The history of our knowledge of the propagation of Cholera can be divided into two periods. I. From the year 1830 to 1849, and II., from 1849 to the present time.

This first period is distinguished according to the metaphysical tendencies of that time, more by abstract doctrines and the statement of facts without connecting causes and effects, than by any systematic attempt at scientific investigation. We find after every epidemic in every part of the world the medical profession divided into two great factions, contagionists and anti-contagionists; and their respective opinions, formed on accidental and general impressions, or through prejudicial teachings of men high in professional authority, and never discussed on the merits of their own case, but only on the weakness or shortcomings of the others, have found the best reflex in the public opinion on the prevention of Cholera. The people, bewildered by the great mortality of every Cholera Epidemic and the apparent ignorance of the physicians, resorted to such extraordinary preventive measures as the wearing of amulets and drinking Cholera drops, to fumigating the air with suffocating bonfires, and sending tobacco-smoking soldiers through infected streets. In some places of Italy the fanatic ignorance has reached such a point, that physicians and Jews have been murdered upon suspicion of poisoning the wells and producing the disease. But prominent and good observers of the nature of the disease have been found at all times, and even this period of conclusions post facta has produced some records and essays on Cholera which have been made the basis of future exact and natural scientific investigation.

To English writers, as Jameson of India, Simpson, Parkes, Budd, and many others, more than to all continental writers of that period, belongs the honor of a correct and comparatively true interpretation of the causes of the Propagation of Cholera.

A curious historical fact may be here briefly alluded to: The very first report made in Europe, 1829, by twenty-four Russian physicians sent by the Russian Government to the Asiatic frontier to study and observe the nature of the approaching disease, and published by Prof. Tilesius, 1830, has the following conclusion: "I do not know much about fixed and volatile contagion, but the fact seems to me very important, that Cholera is positively infectious through privies."

The epidemic in Great Britain, 1849, brings us to the second period—to the period of our more exact and scientifically connected knowledge of the causes of Cholera.

Snow's and Simon's very valuable and positive demonstration of the influence of drinking water from wells and aqueducts polluted with sewers from privies, must be considered as the first link in our future chain of exact knowledge.

Farr's excellent tables on the difference of mortality of Cholera according to the elevation of the ground, are also truthful contributions to our exact knowledge, when the nature of the ground and the communication are comparatively the same.

A very interesting feature of the epidemic in England, 1849, was the attempt of eminent men to give a distinct, fixed expression as to the nature of Cholera poison through researches of the microscope; but it failed totally, and had the evil result of bringing this doctrine into distrust, particularly amongst the eminent men in this country. The fault was not in the inert truth of the fact, but in the unmethodical and unsystematical way of investigation.

Britton and Swayne reported to the Bristol Society of Physicians that they found ring-formed objects which have not been discovered in other evacuations. Budd examined the drinking water of the infected districts and found similar objects, each of the gentlemen giving different names, according to his own impression, as, Cholera cells, Cholera fungi, and Cholera sporuli.

Baley and Gull, in a report to the College of Physicians, in London, denied the existence of every one of the objects seen by the Bristol Committee as characteristic of Cholera, and maintained that they might have been introduced into the system by food or medicines, and were not to be found in Cholera foci.

A later German critic believed that the Bristol Committee had seen eggs of helminths, and another eminent microscopist exclaims in despair, that he cannot make out what the different objects were, these different men in England have seen and described.

The great idea of fermentation so ingeniously illustrated and described by Liebig in his Chemical Letters and the Doctrine of the Origin and Growth of Spores, a distinct science, so extensively cultivated in France and Germany, seems not to have been the foundation relied upon in the English investigations.

The epidemic, 1854, found in England superior sanitary officers, with excellent advantages derived from the published Report of the Causes of Mortality of Cholera in 1849, and prepared with practical preventive measures.

In Germany, 1854, we find the old difference of opinion on theoretical points; no sanitary preventive measures whatever, care and hospitals for the poor, physicians and medicines free of charge, a police order against sour beer, unripe fruits, and old meat; excellent measures, as Pettenkofer remarked, the whole year round, but it was nothing specific against Cholera.

The intensity of the epidemic in Bavaria, 1854, was great; 16,000 well marked cases, with the usual mortality of 55—60 per cent. This epidemic was fruitful of great scientific investigations and the most important practical results.

Professor Pfeufer, the well known clinical teacher and the most experienced in personal observation of Cholera all over Europe from 1830 to 1854, was in 1854 as non-committal on the causes of propagation of Cholera in his clinical lectures, as we have seen our distinguished Professor Clark in 1866; but one thing was clear to his mind, that this problem could never be successfully solved by sanitary officers or physicians alone; that the specific laws, regulating this universal specific and uniform disease, could only be interpreted by the high-priests of medicine—that is, the leading minds in natural sciences.

Meteorology, Geology, Chemistry, Zoölogy, Botany, Microscopy, and Pathological Anatomy, were represented in this scientific commission by the most eminent of German natural philosophers; sanitary officers and physicians, in distinct contrast to former and later reports, taking only the part of co-workers and faithful reporters of facts, but not of expounders of "post hoc, ergo propter hoc" conclusions.

The axioms laid down by this commission have become, as you will easily perceive, international property. The leading and comprehensive mind of this commission,

Pettenkofer, who is a strictly positive and ingenious scholar, has become, by his unsurpassed and excellent essays onthis and similar subjects, the attractive centre of all medical and sanitary authorities of the present time.*

I may close my remarks on this general subject with the same words as I closed a communication to the Sanitary Committee of this city more than a year ago. "The value of this scientific report has made it a standard and a guide for future investigations and actions."

The actions, as you well know, have been faithfully and successfully executed by the Sanitary Committee—the future investigations belong to the specialist of our profession.

In bringing before you the leading points essential to produce Cholera, I shall keep myself strictly to the three fundamental laws laid down by Prof. Pettenkofer, leaving out the fourth law—the individual disposition—the physiology and pathology of which has not advanced enough for exact knowledge.

I shall endeavor to illustrate each point by our actual and practical experience, acquired in the last and former epidemics.

I. The specific germ is propagated in Cholera Diarrhœa, or in the evacuations of persons coming from places infected with Cholera.

This term, "specific," has been given to Cholera by a thousand-fold repeated observations of its nature, and by hundreds of excellent observers.

I will now inquire into the exact nature of "specific germs," in contrast with other intestinal evacuations.

The discharges of Cholera, and the rice-water and primary diarrhœa, have invariably an alkaline reaction. The diarrhœa, in contact with other organic matter, particularly excrements, has the power of undergoing a chemical process (fermentation), producing an enormous *fauna*, in contrast with other evacuations under similar conditions—a fact described after careful comparisons by Prof. Siebold, the greatest zoologist of Europe.†

This diarrhœa, in itself harmless, undergoes first a chemical process that gives it the property of a metabolic poison, with reproductive power; secondly, this metabolic poison has a time of incubation, exhausts its effects on the organism with one attack, that is, imparts to the same an immunity for a long time after. Ingenious and successful experiments of infection on animals, producing the characteristic symptoms and anatomical alterations, made by Lindsey in Edinburgh, and by Thiersch in Munich, under the direction of eminent chemists and anatomists, give the most important evidence in favor of the term specific, in contrast with other evacuations not having this infecting power, and in contrast to absolute contagious diseases like measles, scarlatina, smallpox, producing apparently at once a "ready-made" contagion. Without anticipating, I may briefly state here, that Pettenkofer and Thiersch, in 1856, advanced the idea, that this cholera ferment must finally produce an organic cell or spore, embodying the propagating power, and that Liebig, in a popular essay,‡ expressed his decided opinion that the whole cholera process is to be found in a yeast-spore. I would certainly rely on such interpreters of natural phenomena in organic chemistry. I may plainly ask you, "Who knows better?"

This distinct characteristic symptom for Cholera and diarrhœa may have been sufficient for the term specific; but the last epidemic of 1866, in Austria and Prussia, brought forward the most interesting and surprising facts, corroborating fully the above investigations and opinions. I hope that in due time a more competent person will be found to explain to you the microscopical details, and I will to-day only lay before you the most important results with the drawings of both works.

Klob's studies on Cholera, published this year in Vienna, have been made with the view of comparing the different consecutive stages of Cholera, from diarrhœa to rice-water stools, with the evacuations of other patients, taking dysenteria, typhus, marasmus of children, simple diarrhœa, and healthy fæces, as the bases of his microscopical and comparative chemical investigations. It is a well known fact to you, that spores in different forms have been found in muguet, and sarcina in the stomach, and certainly in the mucous membranes of the intestines, connected with physiological functions and pathological processes; but Prof. Klob discovered in Cholera dejections such enormous quantities of spores and fungi extending gradually from the œsophagus over the stomach down to the intestinal canal, as to form a perfect gelatinous substance in the intestines (called in zoological terms "Termo Zooglea," spore-bed) and not to be mistaken for mucus or albuminous aggregates.

This form of fungi, its quantities, and its distinct, characteristic, genetical progress, has never been before observed or described, according to Klob, by any other authority, in the intestinal discharges, from the first slight discharge to the rice-water stools. Klob describes the different consecutive phases of the organic life of the spores, and maintains that in the last stage they have lost their peculiar movements, and losing the characteristic aspect, undergo the decaying metamorphosis of all spores which is called by zoölogists bacterian gelatina.

Klob promised to publish in his next paper the results of experiments with the characteristic Cholera fungi in regard to its breeding properties.

Independent of Klob, in Vienna, and in the same month, February, 1867, we find published at Berlin (Virchow's Archiv,) by Dr. Thomé, Professor of Botanical Zoölogy, the discovery of a new exotic yeast-spore, specific to Cholera, bred, nursed, and fructified in the different stages of Cholera and diarrhœa, in living persons, described, defined, and designed in accordance with Klob's results, only more practically characterized, and the spore's lifetime more brilliantly interpreted and illustrated. With true scholar-like enthusiasm, he baptized the new foundling with an endless number of Greek and Latin names.

For the careful student of Cholera, the origin, existence, and decay of this spore, are the most interesting photograph, a perfect miniature picture of the laws regulating the propagation of Cholera, as will be seen by taking into account the necessary time to fructify (represented as incubation); the tendency to multiply and fructify, when taken from the first stages of diarrhœa (a danger long ago pointed out by Pettenkofer); the intensity of multiplication, under more or less favorable conditions of fermentation (expressed in Pettenkofer's infectious focus); the shrinking and immediate stopping of vitality in the least contact with mineral acids and metallic salts, and the perfect disorganization of the spore under the influence of 70 degrees Reaumer (prototyped as useful disinfectants); the relative insensibility and continuation of vitality under contact with alkaline solution (demonstrating the insufficiency of chloride of lime, so long recommended by sanitary officers); and a limited period of the spore's lifetime (the exact experience laid down in the Bavarian report of the limited time in which certain localities and their inhabitants are exposed to Cholera morbillity, and after this time the existing ferment has lost its specific danger).

The most important result of Klob's and Thomé's

* International Cholera—Conference at Weimar.
† Report on Cholera, by the Royal Bavarian Commission for Scientific Investigation, Munich, 1857.
‡ Augsburg Allgemeine Zeitung, 24 Jan., 1866.

investigation the fact that in the last stages of Cholera the spores are lost, their specific form, vitality, and have already undergone a decomposition, *not* exclusive, idiopathic of Cholera. Thomé could never succeed in cultivating and fructifying Cholera spores from the last stages.

We are not without analogous observations in daily practice: the epidemic cattle-plague, the infectious inflammation of the spleen (Melzbrand), have been positively explained and demonstrated by the presence of specific spores. The grape-vine and potato disease have each their defined and classified spore.

Thiersch made it an axiom for all metabolic poisons that the time of their propagating possibility was limited. There can be no doubt that scarlatina, measles, and hooping-cough have their times of contagiousness and non-contagiousness, only not so fully studied and demonstrated as in cholera.

The studies of incubation and quarantine are inseparably connected. There was never a Cholera quarantine in this country, from the first establishment to the present day. Quarantines have never been overleaped by the Cholera poison; the doors have been ignorantly left wide open. Cholera patients have been scrupulously guarded,—very innocent parties; but infected and apparently healthy passengers have been discharged during the time of incubation, *positively the most dangerous parties, propagating by their cholera-fructified discharges*, as disseminating foci, the disease as quick as railroads and steamers will bring them. From the ignorance of this law of propagation we are enabled to explain all the "mysterious subtlety of the volatile cholera-poison," so often alluded to by sanitary officers.

The infection of Ward's Island, November, 1865, by a nurse discharged from the cholera ship "Atlanta," and readmitted for a sore foot on Ward's Island, never suspected or treated, is fresh in the recollection of all.

Pettenkofer, more than twelve years ago, pointed out the great danger of slight diarrhœa, as cause of propagation,* and Klob's and Thomé's experiments have confirmed it as exact knowledge, that the last stage (rice-water) represents the state of the disease emasculated (non-contagious).

The many puzzling quarrels of contagionists and non-contagionists must be explained by these facts; the striking exemption of physicians, nurses, and washer-women, in regular Cholera hospitals, where mostly the last stages are brought in, is now better understood, and the mysterious, intense, volatile poison, supposed as propagated through distances, in the air, will invariably be found to have a very limited and localized focus established by a specific, perhaps hardly perceptible—diarrhœa.

Quarantines may be entirely abolished as impracticable for international and commercial intercourse, and disinfectants only relied on; but I warn you against the following lesson, taught to us in the Report of the Board of Health.

"Cleansing of the emigrants and their baggage, but not the absurdity of protracted detention, testing the limitation of infection self-productive, are required in the most absolute sense for the security of the public health, and scarcely less for the welfare of emigrants themselves." †

Obedience to the laws of nature may sometimes be inexpedient and impossible; but the above opinion could only have been formed in ignorance of our present exact knowledge.

The connection of disinfections with cholera-diarrhœa, so well known by the doctrines of Pettenkofer and great practical successes of sanitary officers, has been ingeniously confirmed by the experiments of Thomé; but the first case of infection in a given locality (house or institution) discovered, and disinfection is no protection any more for the inhabitants of the same place; *always practicable, always justified*, it leaves the people (inside the focus) to the mercy of their own personal resistance, differing only in time of incubation, and protecting the new arrivals from the action of the specific poison, and preventing further propagating possibilities.

The disinfections at Blackwell's Island, justified by every experience, and executed with practical promptness, are, in facts, dates, maps, time of morbillity and mortality, the best proof of the perfect inaction of disinfection at such a late period of the disease. Greater mortality has been perhaps prevented by hygienic measures ordered, making individual persons more resistible against the disease, but the specific cholera-poison has taken its usual time of waving intensity, for about four weeks after, independent and undisturbed by disinfections, it was limited only by the naturally acquired immunity of the inhabitants. I may safely assert that the conclusions drawn and indorsed by excellent names in this city on the Blackwell's Island disinfection, will at once be repudiated by Pettenkofer, as not warranted by our present exact knowledge of the natural course of the disease.

I come now to the second essential point for Cholera epidemic:—

II. *A soil impregnated with organic matter and permeable for air and water to a certain depth.* (*To the depth of the sub-soil water.*)

To meet in advance certain objections I must explain that the word 'soil' must not be exclusively taken; it is only in the largest scale the representative idea of certain chemical processes in combination with water and air. A sponge with a specific diarrhœa, a wooden bed-chamber, clothing, a wooden drain-pipe in an emigrant ship impregnated with specific diarrhœa, exposed to humid air, have been over and over again admitted by Pettenkofer as small, very circumscribed infectious foci. I must further mention that the objection made to the whole doctrine of this second point by Drasche, and quoted in Prof. Clark's Lectures and Dr. Burrall's book, has been already fully contradicted, 1861, as unfounded on facts.*

The comprehension of these differences of soil, in connection with Cholera diarrhœa, must for ever abolish strict contagionists and non-contagionists.

The soil, as the natural receptacle for human excrements, is, under the above conditions, the great chemical ferment-basis for spore-breeding, so beautifully imitated in Thomé's laboratory; while in contrast, the impermeability of the soil for water and air represents the chemical process so well known as Mummification, or Local Immunity against Cholera.

A number of charts, published by Pettenkofer in connection with the Bavarian Scientific Report, 1854, represent in differently-colored lines a large number of places inflicted with or exempted from Cholera, according to the permeability or impermeability of the soil for water and air, independent of mineralogical aggregations, but always influenced by physical compactness or porosity of the ground. Similar constant old exemptions have been observed in many places of the world, but never understood or explained on their scientific relations.†

* Unanimously adopted by the Cholera Conference, in Constantinople, March 21, 1866. † Pages 156, 157.

* Journal f. Biologie, vol i. page 11.

† Pettenkofer complained in one of his late writings that the charts are so little known amongst sanitary officers; they will have formed the most interesting feature in the Cholera Conference at Weimar.

These charts will definitively answer Prof. Clark's question in his lectures on Propagation of Cholera. Why, if Cholera is contagious, is it only contagious in Cumberland and Columbia, and not in other places where infected people have been communicated with, without producing an Epidemic? The infected or exempted localities in Pennsylvania must logically find their places under the blue or red lines of Pettenkofer's charts, but more than that, a study of the facts and ideas expressed by these differently-colored lines, based on unsurpassed exact investigations, makes us independent of all diffused generalities, as Cholera-fields, dampness, dirt, ill-ventilation, etc., helping only as intensifying, but never as producing causes.

We find this fact illustrated in our daily experience. Governor's Island and Hart's Island, U. S. military posts, as well kept as any similar places in the world, afflicted with Cholera. Tybee Island, a model of ventilation, we find a hot-bed for Cholera. Andersonville and Libby prison, verily cholera-fields, without the least suspicion of the disease.

An ill-ventilated, crowded tenement-house, with extraordinarily dirty inhabitants, may safely overcome the specific germ brought there if their excrements are washed constantly with fresh water, neutralizing as the most natural disinfecters the ferment process of a permeable soil; or immunity may take place, if their privies by fortunate accident are located on a piece of ground, where, by impermeability to humid air, mummification must take place. A excellent country-house—on porous soil and with unexceptionable sanitary inhabitants and regulations, may be visited by an unsuspected specific diarrhœa—the privies, in the house, behind or slightly inclining against the house, and a cholera-field is produced—a subtle mystery in general sanitary expressions.

Farr's Tables on the Influence of Elevation on Mortality of Cholera are the true index of actual facts, when the soil is equally porous, and the specific germ is disseminated through the soil.

Medical officers in India and the Crimea give very instructive lessons of the great danger of privies situated higher than the camping ground. The dissemination of liquid matter in a porous inclining ground takes place, not alone to a relative large extent, but with great rapidity. I know a case from personal experience, where two old bedridden persons in a village, without the least personal communication from without, both died in twenty-four hours of Asiatic Cholera; 200—300 feet above in a straight line a cholera focus existed. I reported the waves of the wind as the communicating medium; but Pettenkofer, not believing in dissemination of Cholera through the air at such distances, found by the aid of the axe and the shovel, that the greater part of the liquid excrements from the house above reached their last resting-place underneath the house so mysteriously afflicted with cholera.

In such exceptional cases the soil is not only the producer, but also the propagator of the specific infection to some distance, without the necessary personal intercourse. I suspect the house epidemic of the Broome street lawyer accused of a damp basement to have a similar specific connection.*

Pettenkofer's personal investigation and description of the Cholera in Switzerland gives us the facts of an intense epidemic in a high mountain village, with perfect immunity for the villages below; the difference in the permeability of the soil determined the infection or exemption. Cholera is independent of height or depth in an absolute sense of the word. Alluvial soil has been found to exist on the Alps as well as on the top of the Pyrenees. The greatest mortality in Europe, in proportion to population, was amongst the thousands of laborers during the building of the great Somering Mountain Railroad.

Pettenkofer visited this place. Besides the necessary conditions for Cholera—specific germ and porous soil—their terrace-like built huts had invariably their privies behind and above them. Fresh mountain air, unpolluted spring-water, regular employment, and wholesome food, had hardly any mitigating influence in presence of this ignorance of the laws regulating the propagation of the specific cholera-poison.

You will, of course, ask the question—How can Cholera prevail with fermentation as the fundamental principle, which never can take place in freezing temperatures many degrees below zero? In Russian, French, and German cities privies are *in* the houses or cellars, well protected against such low temperature; and Pettenkofer initiated the sugar fermentation successfully in such places during winter time. Open countries, and I believe the United States, with different arrangements for privies, have never been visited by Cholera during the winter season.

The greater part of this city (New York) is above the malign influence of a permeable soil in relation to epidemic Cholera. Our privies, constantly flooded with fresh water, are self-disinfecting, fermentation-preventing institutions. A case infected outside may end fatally in Madison Avenue, and by the very limited infectious focus of linen and clothing infect the nearest persons accidentally; but that powerful ferment (specific miasma) producer—the soil—is harmless for the greatest part of this city.

This, my personal opinion, I expressed long before the outbreak of Cholera in this city, and I see it fully confirmed from the mortality in streets and houses* during the last epidemic. No allusion is made or conclusion formed in the Report for 1866 on these, for many of our fellow-citizens, so important and consoling facts.

I give you the analogous experience made in my own native city, Munich, 1854, to justify my deliberately expressed opinion. During the whole intense epidemic, two houses, a poor-house and a penitentiary, situated on porous soil, surrounded by Cholera, without any restricted intercourse, without any disinfectants, the specific germ introduced (by light and fatal cases), the Cholera never took hold in the slightest degree, amongst the hundreds of generally susceptible people of this institution; a remarkable and surprising exception! Springs rising on the top of the hill were running in their course to the river below, beneath the soil of the two large buildings, and prevented, by constantly fresh water, the genetical and dangerous growth of the exotic sporet—the product of the specific Cholera fermentation.

Besides the striking analogy of these two institutions in Munich, and our Croton-water washed privies, such cases teach us the moral lesson, that sometimes apparent deviations in facts, with exact investigations, become convincing proofs of fundamental truths.

The practical conclusions on this second point are covered mostly by the well known doctrines of the constant preventive disinfection of every ground, before suspicious diarrhœa is contaminating the soil.

The plans in building of dwelling houses in relation to privies, the direction of cholera fugitives, may be guided by the exploration of the physical aggregations

* Cholera Report of Dr. Harris for 1866, page 167.

* Metropolitan Board of Health Report, pp. 283, 284, 85.

† In contrast to the spore produced by Cholera nostras (Virchow, Archiv, February, 1867.)

composing different soils. The selection of quarantine grounds for slightly infected persons has to depend entirely on the broad comprehension of this part of our exact knowledge of the causes of cholera.

In intimate connection with the study of the fixed composition of the soil is the third essential point for epidemic propagation of Cholera, as follows:

III. *Occasional increase and variations of humidity in this alluvial soil, manifested in the most plain and reliable manner by the different elevations of the sub-soil water (Grundwasser), the greatest danger being when the sub-soil water begins to recede from an unusual height.*

This doctrine covers the ground for timely (temporary) disposition of certain localities, cities, streets, or houses, and will be the scientific answer to the often-repeated, vexed question discussed by sanitary officers and newspapers—Shall we have epidemic cholera this year, or shall we, independent of quarantine and disinfectants, escape the danger of a well-disposed soil in connection with the fructifying growths of the imported exotic spores?

I say it will answer this question months in advance with great decision and scientific accuracy,* as Pettenkofer's interesting researches for the last twelve years, on this original subject, have taught, but only hydraulic engineering and geology combined can guide clinical and sanitary science in this direction.

Let me repeat, in a few words, the great ideas of the whole doctrine laid down by Pettenkofer from the experience of thousands of cases, from the personal investigations of over thousands of miles of different countries, from the intuitive studies of writers of all nations, guided only by natural science, and interpreted with the thoughts of a reflecting mind:—

1. The absolute necessity of a specific germ represented in the evacuations;

2. The presence of a well disposed breeding-place most extensively expressed in the alluvial soil;

3. The favorable or unfavorable time to bring this germ to a specific ferment, dependent on the well-defined local variations in the elevation of the sub-soil water.†

More, a great deal more, has yet to be learned; but we have a right to speak of *some* exact knowledge of the causes of Cholera.

ANEURISM OF THE ABDOMINAL AORTA.

By EDWARD T. CASWELL, M.D.,

OF PROVIDENCE, R. I.

In an elaborate and instructive article upon Internal Aneurism in the American Journal of Medical Sciences for January, 1867, by Dr. Liddell of New York, it is stated that abdominal aneurisms sometimes break into the left pleural cavity, and no reference is made to any other disposition above the diaphragm of the contents of the sac of an abdominal aneurism. In the following case an outlet was found into the right pleural cavity, and as the writer mentioned records no such instance, I infer that it is comparatively rare.

William A., of about thirty-five years of age, and of spare habit, had been treated for some months by several physicians for complaints which had been ascribed by one to the stomach and by another to the liver. In the month of September last I was requested about two o'clock in the morning to visit him, the messenger stating that he was suffering from "a swelling in his stomach which throbbed." As he resided some distance out of town I sent him an anodyne and promised to see him early in the morning. On arriving I found that he had died at 7½ A.M. He had been employed as engineer on a tug-boat, and was an industrious and temperate man. I learned that he had complained, while on his boat at noon on the preceding day, of severe pain, apparently in the epigastrium, and had been put ashore. He remained until 5 P.M. near the landing, and then walked an eighth of a mile up a hill to his house and then up-stairs. During the night he suffered intense pain and had, as it was stated, "two or three attacks of trembling with stiffness of the limbs." He got but little sleep; at times he would walk up and down in great distress, and then would lie down, but he could not remain on the bed. Ten minutes before he died he walked across the room and conversed with members of his family.

I made an autopsy twenty-six hours after death, and the following statements are taken from my own notes and from those of Dr. Mason, who kindly assisted me. Upon opening the thorax blood was seen to issue from the right thoracic cavity, and when the sternum was removed the whole cavity seemed filled with clotted blood and serum. Two quarts were removed. The lung was greatly compressed; indeed it seemed scarcely larger than my fist. In the posterior mediastinum, and extending down the course of the œsophagus, there was a firm clot which passed down through the œsophageal opening in the diaphragm. The left thoracic cavity presented nothing abnormal save some old pleuritic adhesions. The heart and the pericardium were free from disease. On inspecting the abdomen a large firm clot was found around the posterior cardiac surface of the stomach, glueing it and the intestines together. The adjoining portions of the peritoneum were much thickened. On breaking up the clot the aneurismal sac was exposed. It was developed about the cœliac axis, just above the superior mesenteric branch of the aorta, and projected from the left side of the latter. It opened into the aorta by a single mouth, three-quarters of an inch in diameter. It was composed of all the coats of the vessel and was somewhat larger than a goose-egg, having two pouches developed in its walls, the larger of which was about two inches long and one and a half inches in diameter. It was lined with several layers of lymph, and these in one portion formed a projection into the cavity—a stalagmite growth as it were—about an inch broad at its base and projecting three-quarters of an inch into the cavity. The walls of the sac were in some places quite thin, and the rupture had taken place in its upper or diaphragmatic portion. Being unable to rupture the peritoneum the blood had found a way for itself through the connective tissue, along the fibre of the œsophagus; thus passing up into the posterior mediastinum, had found some weak spot in the right pleura and poured itself out as I have stated, into the right thoracic cavity. The aorta was atheromatous, and deposits of a similar nature could be felt in the radial artery on both sides; portions of the aneurismal one were also found in a like condition.

It seems as if the diagnosis of an aneurism could have

* Vide Journal f. Biologie, 1866.

† A full exposition of all facts connected with point No. III. would have too much extended the purpose of this paper; but it may be interesting to state that the International Cholera Conference in Constantinople has acknowledged a real probability of Pettenkofer's opinion (Answer XXVI.), without knowing at that time that Pettenkofer, in his critic on "Macpherson's Cholera in its Home," has made the endemicity in India as dependent from the same natural law as a temporary epidemic is in Europe or in the United States. The Weimar Conference a few weeks ago, has unanimously adopted the truth of this point (No III.) after a brief personal explanation of its details by Prof. Pettenkofer; dissenting opinion (from Russia), based on negative results, being fully outweighed by the corroborating researches of Prof. Pölsch, extending his investigations of the sub-soil water, over six years in St Petersburg, and finding the relative influence on epidemic Cholera absolutely true.—*All. Zeitung, Mai*, 1867.

been very easily made in this case, if any careful examination had been instituted. That it could have attained such a development, and escaped detection, seems almost impossible. It would be interesting to determine if we could discover the relation between the subjective symptoms the last fifteen hours of life with the pathological condition developed, but that can only be a matter of speculation. It seems every way probable that the patient must have survived the rupture of the sac for some little time.

This instance of an abdominal aneurism opening into the thorax may perhaps with propriety be placed in apposition with a specimen to the Pathological Society of London by Mr. Pick, and reported in the *Medical Times* and *Gazette* for January 12, 1867. In this case a thoracic aneurism of large size discharged its contents into the peritoneal cavity. The evacuated blood followed down the muscular fibres of the œsophagus and penetrated the peritoneum close to the cardiac orifice of the stomach.

REMARKS ON THE TREATMENT OF FRACTURES OF THE PATELLA.

WITH A DESCRIPTION OF THE LATE DR. THOMAS TURNER'S APPARATUS.

[By FRANCIS V. WHITE, M.D.,

OF NEW YORK.

Sir Astley Cooper* believed ligamentous union resulted in fractures of the patella, generally; rarely osseous. He arrived at this conclusion, from his experiments and observations on the rabbit and dog, having produced fractures of usual varieties in both; in different periods of time noted efforts of nature in reparation; he states that there is no callus to interfere with the joint; and advises that the surgeon should make the ligament short as possible, for the welfare of the patient, in transverse fractures. He presents two modes of treatment: 1st, he places the patient in semi-recumbent position, with the extremity on a well padded posterior splint, leaving the knee exposed, to combat inflammation. When proper, he bandages to the knee, then makes a sufficient number of circular turns below and above the joint, approximates these and thereby the fragments, by broad tapes at right angles and under these on each side, being tied together. He cautions any violence in bringing the upper fragment down. 2d, the leg being bandaged, he places a leather strap around thigh above the fracture, from this, a strap around the sole of the foot up to the thigh-strap and kept in place by tapes.

The treatment continues five to six weeks, then cautious passive motion is made, until use of the limb is acquired. He says he saw the patient of M. Chopart at Paris, who appeared to have bony union, and mentions a case published by Mr. Fielding of Hull.

He considered the absence of perfect coaptation of the fragments in these fractures, to be the cause of non-ossific union.

Mr. Gulliver,† also made elaborate investigations of the powers of nature, in the artificial fractures he made of the patellæ of rabbits and dogs; concluding, in fracture of the patella, if the aponeurosis is entirely ruptured, no bony union results. The inter-substance is vascular, therefore the absence of bony union is not from proper nourishment. Bony union results from perfect adjustment of the fragments, if the aponeurosis is not entirely divided. Fibrous tissue precedes bony. His object was to demonstrate what results we might expect in treatment of fractured patella. He suggested no apparatus.

Mr. W. Adams,* in a paper before the Harveian Society, refers to having presented before the Pathological Society of London in 1850, two specimens of fractured patella.† One, true ligamentous union; the other an ununited fracture. He had not seen a separation of over one and a half inches in true ligamentous unions, usually half to one inch. He alludes to Mr. Holthouse's‡ specimen, presented subsequently, of two and a half inches. What he calls ununited fracture, previously was considered elongated ligaments; he proved it to be a thickening of the fascia, and aponeurosis, and bursa. Length of second specimen was five inches, a line to one eighth of an inch in thickness. Of thirty-one specimens he examined in the six principal museums of London, fifteen were ununited, twelve ligamentous, and four obscure from being dried. He suggests in the treatment, 1st, subdue inflammation; 2d, approximate the fragments as soon as possible; 3d, retention sufficient time, to insure true bone, or short ligamentous union, avoiding eversion of the fragments, and a slipping of the fascia, aponeurosis, etc., between, that being the cause of ununited results. Recommends M. Malgaigne's apparatus in treatment. Notes its extensive use in France; that no serious inflammation was produced by its use; generally borne without inconvenience or pain. May, 1853, M. Malgaigne informed him, the hooks had been used eleven times with complete success. He used them in one case of ununited fracture of patella of long standing, detaching by subcutaneous section the aponeurotic structures, coaptated the fragments, with the hooks. Borne for two weeks without inconvenience. Greatly improved. Result not given.

Mr. Malgaigne § has an ably written article on fractured patella. He thinks thirty to forty days' treatment sufficient for fibrous or bony union. Calls attention to the danger of anchylosis; as varying, from degree of inflammation, time of confinement, pressure by the apparatus, whether the apparatus was applied before or after inflammation. The greatest separation he knew of, was the case of Sir A. Cooper, viz. over four inches. Alludes to Gulliver's investigations, also Sir A. Cooper's. Never applied apparatus until inflammation was subdued. Removed it in forty days, anchylosis disappearing shortly.

Observing the inefficiency of the apparatus for ossific results, he invented his hook apparatus, which consists of two steel plates; inner one, one and a fifth inches in length, on account of the obliquity of the patella, two-thirds of an inch wide, free extremity bifurcated into two very sharp hooks, one-third of an inch apart; outer one, one inch long, same width as inner one, hooks two-thirds of an inch apart. Sliding of the plates upon each other regulated by a screw. Apply the hooks of inner one first, just below the point of the patella, drawing the skin down somewhat, then coapt the fragments, drawing the integuments up, insert the outer hooks just above the base, using force, by the screw; an improvement of M. Charrière, which the patient cannot tamper with, the plates slide upon each other approximating the fragments. The only ill he observed, was that the upper hooks slipped about the seventeenth or twentieth day.

§ M. Malgaigne on Fractures, Packard, 1859, p. 599.

Dr. Packard,* of Philadelphia, publishes a case of transverse fracture of the patella, which he treated successfully with the hooks. He, assisted by his friend, Dr. Brinton, could not perforate the patella to the joint, by violence, with the hooks, on the cadaver. He believes if the hooks are properly applied, there is no danger of the slipping Malgaigne spoke of. He concludes from his case, that there is no fear of ulceration or necrosis. The pain is not severe in the application of the hooks. Anæsthetics could be used, if necessary. Esteems the hooks the best appliance for firm coaptation of the fragments. Other modes, apt to have a tilting-up of the fragments, viz. a V gap between.

Coaptation, tested by hooks and bone moving as one mass. Dr. Ellis, Boston, informed him of the estimation of the hooks, "They are not liked here, and never used." Dr. Noyes, New York, wrote to him, 1854, that Dr. Buck had used the hooks, and that such inflammation resulted in two weeks, that they had to be removed. Abscesses formed about the joint, which prolonged the treatment twice the usual period. Result, bony union. The joint was quite rigid when the patient was last seen. "This case was pretty generally known among New York surgeons, and its results proved condemnatory of the hooks." Dr. Packard† publishes the same case, refractured, about six months subsequently. On the first occasion, he applied the hooks the eighth day, retained them thirty-one days. There was good use of the limb in two months' time. Second time retained them twenty-nine days.

Eighty-six days following, inter-substance was not more than half an inch. No halt in gait, only in going up and down stairs. Believes he had bony union on first occasion, as a sharp crack was observed when last fracture occurred, and from his manipulation of the fragments he was satisfied of it.

Campbell de Morgan,‡ F.R.S., Surgeon, Middlesex Hospital, states M. Malgaigne's hooks had been used frequently and satisfactorily. Mr. Henry, his colleague, directed his attention to cases where there probably were bony unions. He appears to esteem the hooks as highly as Dr. Packard. Relates a case where both patellæ were fractured; one treated by the hooks; other, by position. Result of former pretty closely approximated; latter, the separation from half to three-quarters of an inch. Another case; female, far advanced in pregnancy; hooks were applied; nothing unfortunate occurred; still under treatment. Only objection he makes is the tendency to a V gaping of one-eighth of an inch superiorly, which, he remarks, can usually be avoided by altering direction of the upper hooks. If the parts are kept at rest, he considers the hooks free from irritation, as metallic sutures are.

G. E. Pyle,§ House Surgeon to Middlesex Hospital, records eight cases treated by Malgaigne's hooks; commends them; closes with a synoptic table of sixteen cases, eight treated by Malgaigne's hooks, and eight by the usual means.

J. M. Chelius,‖ University of Heidelberg, mentions the separation in transverse fractures of the patella may be four to five inches. Crepitation is not observed, as the fragments cannot be immediately approximated; may, in vertical, oblique, or splintered varieties. Quotes Gulliver's conclusions. Believes treatment results in a fibrous inter-substance, on account of the difficulty of perfect coaptation of the fragments. He condemns as unsuitable, especially tight bandages, as producing anchylosis and adhesion of the patella with the femur, also liability to atrophy of quadriceps femoris, a termination to be deprecated more than a long inter-substance. His treatment, mainly by position, the extremity flexed on the body, and the body on it, pillows being placed under the extremity and the trunk, binding lower portion of the thigh, and fastening to the bed, the fragments being thus pretty easily coapted; or a long posterior splint, with footboard well padded. Cites Alcock's application of adhesive plaster, with his mode, as advantageous. If there is powerful muscular action to be overcome, his appliances are complicated and cumbrous, viz. the fragments being coapted, pads are placed above and below, and retained by figure-of-eight bandage; over the whole an invaginated bandage is fixed longitudinally.

Liston asserts,* in transverse fracture of the patella bony union is rare, "one not to be expected or favored," Treatment by position, on an inclined plane; apply a bandage from toes to above the fragment, not tight. Objects to form figure-of-eight, bandaging over compresses of cork or other material, or straps and buckles.

Skey† advises in transverse fracture of the patella to guard against retraction of upper fragment by quadriceps femoris, by placing the patient in position, or have him sit up in bed, rubs and kneads the thigh from above downwards; if unsuccessful, uses chloroform. When the muscles are relaxed, he applies a bandage from the groin down to a safe distance from the joint, so as not to increase effusion nor tilting of the upper fragment. If a failure, leaves nature untrammelled in a sitting posture. Fixes the lower fragments with a pad of lint, retained by adhesive plaster. Gives no results. Regards ligamentous union as not producing, universally, difficulty of locomotion. Mentions a case of permanent separation of one and a half inches, and locomotion was perfect.

Gibson‡ speaks of the comparative weakness of fractured patella. Prone to refracture; the difficulty, perhaps impossibility, in transverse fractures to coaptate fragments; therefore no osseous union. Inter-substance resulting, remaining soft, is easily torn, for a length of time. Bony union extremely rare. Cites Sir A. Cooper's experiments. Warns of the danger of the fracture of sound patella from strain superinduced.

Miller§ avers that in transverse fractures of the patella bony union may occur, but undesirable, from danger of refracture or anchylosis; thinks a short inter-substance obviates difficulty. Treatment, ordinarily by position; bandages leg, and applies figure-of-eight if necessary; if not, suggests broad leather belts above and below the joint; by cross belts approximating, produces coaptation; or Lonsdale's apparatus, which consists of a posterior splint with foot-piece movable, to accommodate different limbs; in the region of the knee are two vertical bars of iron connected to the splint, each supporting horizontal arms bent at right angles, which slide on the vertical, being arrested by screws to which horse-shoe formed plates are attached by a hinge-joint. Being well padded, bandage the foot and leg to the splint, coapting the fragment; the upper horse-shoe with intervening soft pad is applied first, just above the fragment, not touching the patella; lower plate applied just below, secured by the screws; then bandage the thigh and upper part of the splint; whole limb placed in position by a pillow placed under it. Mode of Dr. Neill, of Philadelphia, is most convenient and

efficient; viz. application of one or more strips of adhesive plaster above and below the fragments obliquely attached to the posterior splint; no strangulation of the limb, as in figure-of-eight bandaging.

Smith* affirms that crepitation is almost impossible, except in oblique fractures of the patella; bony union rare. Advises accurate adjustment of the fragments to obtain bony union; if not, a short inter-substance, for power. Has a specimen of bony union in his cabinet; history unknown. Treatment, viz. Dessault's: strip of muslin, two and a half inches wide, from groin to foot, retained by bandaging the lower extremity; cut two slits in the strip opposite the knee, to pass the fingers through, to coaptate the fragments, retaining them by compresses, with figure-of-eight bandages; then bandage thigh to overcome the muscles; place the limb on a well padded inclined plane splint, thereby favoring muscular relaxation, and return of blood, reducing inflammation. Boyer's: a compress is placed above the superior fragment; by figure-of-eight bandage brought down; coaptation is completed, by figure-of-eight bandage; the leg having been bandaged, bandage the thigh; apply a posterior splint as in Dessault's mode. Prof. Dorsey's is one of power: a well padded posterior splint, length of the extremity; two strips of bandage tacked on the back of the splint; sufficient separation, opposite the knee; the fragments being coapted, and by compresses above and below fragments; held by tying the strips obliquely over them. He believes this will hold the fragments in accurate apposition, but risk of inflammation and ulceration. He thinks Malgaigne's hooks would more thoroughly coapt fragments, but objects to them not only from danger of perforating the joint, but from erysipelas. His best treatment is the application of adhesive plaster, coaptating the fragments, combined with a posterior elevated splint; plaster should be three-quarters of an inch wide, long enough to pass obliquely around the limb; the lower fragment being fixed, apply first strip from behind the tibia, around lower tip of patella, upwards; upper fragment being coaptated, apply strips in an opposite direction, forming two semicircles about the joint; dressed occasionally as indicated; dressings continued five or six weeks; cautious passive motion commenced about the third week. He remarks, adhesive plaster had been employed for thirty years past in Pennsylvania Hospital, by Barton and others, satisfactorily. Attention was recalled to it by Neill, of Philadelphia. Gama, of the Val de Grace, Alcock, of England, and Hamilton, of New York, all approve of it; each has slightly modified it, still using the adhesive strips. Gerdy's plan, liable to cause pain; it is an invaginated bandage, with compresses above and below the fragments, retaining, by bandaging, the whole extremity.

Gross† never had seen complete ossific union of transverse fractures of the patella; speaks of the difficulty of muscular action on the upper fragment, to overcome which is the chief indication of treatment. Apparatus, than which he considers nothing better, is, viz. a well padded tin case applied posteriorly, from middle of thigh to same point of leg; bandage from toes upwards, and from groin downwards, upper fragment being reduced; is confined by adhesive strips, placed around the bone above and below the joint, and connected by vertical and transverse pieces; dressing completed by application of a long, thick, and rather narrow compress, extended around upper border of the patella, confined by two bandages around the joint, figure-of-eight; no danger of displacement. Gives a cut of the mode of Prof. Hamilton, with comment, that it is, with slight modifications, that of Pennsylvania Hospital. He commences passive motion about the third week, repeated every other day, subsequently every day; in four weeks removes the tin splint, applying a posterior leather splint; permits the patient to walk with crutches; guards against early extensive use of the limb under three or four months. Heath:* Treatment not to commence till inflammation is subdued; accomplished by position, having the patient sit up, with the extremity raised, etc.; apparatus, simple splint back of knee, with two strips of adhesive plaster to coapt fragments; or Wood's splint, which is a back splint, with hooks, as fixed points for the bandage to act from, *vide* Ferguson, p. 393, and Druitt, p. 285. Recommends broader splints than generally used, preventing pressure of sides of the knee; well to bandage thigh from groin to control quadriceps femoris. When danger is over to the joint, advises plaster of Paris and starch appliances, alone or with light back splint, for out-patients.

Reports of Hospitals.

CHARITY HOSPITAL, BLACKWELL'S ISLAND, N. Y.

REPORT OF A CASE OF TRIPLE BIRTH.

REPORTED BY CHARLES CULVER, JUNIOR ASSISTANT RESIDENT PHYSICIAN.

DELIA O'BRIEN, a native of Ireland, thirty-five years of age, was admitted to this hospital, March 19, 1867. On Thursday, the sixteenth instant, she first noticed some slight pains during the forenoon, but did not call the attention of any one until about two o'clock, when she felt the waters escaping. She was immediately placed in bed, when a child presenting by the head was expelled before an examination for position could be made. The uterus still remaining large, a hard mass being felt at the fundus, auscultation was resorted to, the placental bruit was heard on the left, and a fœtal heart on the right side of the abdomen; an examination by the vagina revealed the presence of a bag of waters protruding from the os uteri, inside of which the feet of a child were distinctly felt; the rapid contractions of the uterus soon crowded this child down, and it passed rapidly through the well dilated passages, no part being arrested; one dram of the tr. ergot was now administered, which quickened the pains, that were growing less frequent.

The vertex of the third child was felt engaging at the superior strait in the first position, viz. occiput to the left acetabulum. This child, like the preceding, was quickly delivered. Firm pressure was made over the fundus uteri, and the placentæ were cast off; that of the first child being single, the other having a double placenta, to which two cords were attached—one near the edge, after the manner of a battledore placenta, the other cord was attached as usual—each child was inclosed in a separate cavity, and surrounded by membranes of its own. They were all perfectly formed female children, and their combined weight was eighteen pounds and twelve ounces. The entire delivery was accomplished in an hour and a half. The mother had previously had three children, all single births; one of them weighed twelve pounds at birth. She was not in the least exhausted, and declared her ability to walk about. She assures me that there is no hereditary tendency to multiple pregnancies, either in her own family or that of her husband.

Original Lectures.

LECTURE ON CERTAIN MORBID AFFECTIONS OF THE FINGERS AND TOES.

By ALFRED C. POST, M.D.,

PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF NEW YORK.

GENTLEMEN:—There are certain diseases of the fingers and toes, to which I will now direct your attention. The first of these is in common language called a felon or whitlow. It is technically called paronychia, the term being derived from the Greek words παρα, beyond, and ονυξ, a nail. It is an acute inflammatory affection, involving primarily the synovial membrane which lines the sheath of the flexor tendon, and extending secondarily to the periosteum of the adjacent phalanx, and to the integument covering it. It may be the result of a puncture or contusion, or of exposure of the part to excessive heat or cold. It sometimes occurs without any obvious exciting cause. The first symptom is a circumscribed dull pain, referred to the palmar surface of one of the phalanges, and increased by pressure upon the affected part. This pain gradually increases in severity, until it amounts to almost intolerable agony. It assumes a distinctly pulsatory or throbbing character, and is greatly aggravated by a depending position. The severity of the pain is such as to incapacitate the patient for bodily or mental exertion during the day, and in a great measure to prevent him from sleeping at night. When the disease is left to itself, it continues to torment the patient by day and by night, during a period varying from one to two weeks, until the sloughing of the fibrous investments, and the ulceration of the integument, relieve the tension of the inflamed parts, and give issue to a collection of purulent matter resulting from the inflammatory action. At the commencement of a paronychia there is very little swelling, and as the disease advances, the swelling takes place very gradually, in consequence of the density of the tissues which are involved. The swelling is at first confined to the anterior surface of the affected phalanx, and then slowly spreads along the adjacent phalanges, both in a proximal and distal direction. It also secondarily involves the dorsal surface of the affected member, and at an advanced period the dorsal swelling sometimes exceeds that which exists on the palmar surface. Under these circumstances, it is a matter of great practical importance to avoid the error which I have known to have been committed—viz. that of regarding the dorsal inflammation as the main disease, and directing the principal treatment to its relief. Under such a mistaken view of the disease, and the consequent erroneous treatment, the sufferings of the patient are unnecessarily protracted, and the liability to disorganization and deformity is greatly increased. The swollen parts exhibit a blush of redness more or less deep, and the temperature of the surface is elevated considerably above the normal standard.

When a spontaneous opening has occurred, the intensity of the patient's sufferings is relieved, and he is able to sleep. But a considerable time elapses before the pain and swelling subside, and the tenderness on pressure ceases to annoy the patient. Before the part returns to a painless condition, it often happens that the flexor tendons have sloughed, and the patient has thus permanently lost the power of flexing the finger. The inflammation often extends to the periosteum and to the bone, giving rise to caries or necrosis, followed by permanent deformity of the affected member. In some cases, fortunately rare, the inflammation becomes diffuse, extending along the palm of the hand, and up the forearm and arm, sometimes rendering necessary the amputation of the limb. In one case, occurring in the practice of a professional friend, the patient's life was barely saved by amputation at the shoulder-joint.

Notwithstanding the severity of this disease, and the injurious consequences to which it leads, when left to itself, I have always found it amenable to treatment. At a very early period, before any considerable swelling has occurred, the disease may sometimes be arrested by the application of poultices or fomentations, at as high a temperature as the patient is able to endure. But the remedy on which the principal reliance is to be placed, is a free and deep incision extending into the sheath of the tendon. A superficial incision will afford little or no relief; and a puncture, extending into the synovial sheath, and giving exit to pus, will fail to afford the complete and immediate relief which is the result of a free incision. The object of the incision is not merely to give exit to pus, but to relieve the tension of the fibrous membranes which strangulate the inflamed parts, or which have themselves become involved in inflammatory action. The manner of making the incision is a matter of some practical importance. If an attempt be made to open a paronychia in the same manner in which an abscess is usually opened—viz. by inserting the point of a lancet or bistoury, and then cutting out towards the free surface of the skin, the opening will be very apt to be insufficient. The best method is to lay the back of the hand on a towel resting upon a table, and having the finger firmly held in an extended position, to cut boldly with a sharp scalpel from the surface into the synovial sheath, to the extent of half or three-quarters of an inch. If the patient is not under the influence of an anæsthetic, the incision occasions a severe but momentary pain, followed by a smarting or burning sensation, of variable duration, but not usually of great severity. The throbbing and aching pain of the disease is almost instantaneously relieved by the incision, when it is properly made. There may be some question as to the time when a paronychia should be laid open. Most patients prefer waiting until they have passed several sleepless nights, before they make up their minds to undergo the operation. My own opinion is in favor of making the incision at as early a period as the disease can be accurately diagnosticated. I do not wait for the occurrence of suppuration. If this can be anticipated, it will save the patient much suffering, and the wound will heal more promptly than if the incision had been made at a later period. When the incision has been made at an early period, before much swelling has taken place, the only dressing required will be a compress of lint wet with cold water, and wrapped around the finger. But when the incision has been made at a more advanced period of the disease, when there is great swelling, with copious suppuration, emollient poultices may be applied with advantage. But they should not be continued more than three or four days after the operation, as their protracted use produces too much relaxation, and retards the healing of the sore. When the poultices are laid aside, the sore may be dressed with lint spread with a moderately stimulating ointment, as ung. resin, etc. When necrosis or caries of the bone has taken place, the diseased or dead bone may be removed, or the finger may be amputated.

It is rare to meet with paronychia of the toes. The thumb and fingers are the usual seat of the disease.

The disease known as onychia is liable to occur in the toes as well as the fingers. It affects the great toes more frequently than the smaller ones, and I think that

I have observed it more frequently in the thumbs than in the fingers. The disease is an inflammation of the matrix of the nail, and of the adjacent portions of the skin. It is often occasioned by contusion of the distal extremities of the fingers or toes. Sometimes it occurs from constitutional causes. A very severe form of the disease occurs in connexion with constitutional syphilis. The disease known in common language as a "run-round" is a mild form of onychia. The more severe form of onychia is a very obstinate and painful disease, often continuing for years, and showing no tendency to amelioration except under the influence of appropriate treatment. The extremity of the affected finger or toe becomes greatly swollen, presenting a livid red color, with ulceration beneath the nail, and giving issue to an offensive sanious discharge. The nail itself becomes partially detached, presenting a broken and irregular outline, and having a dark color. In its abnormal condition, it acts as a foreign body, and its presence maintains a persistent irritation.

The first step in the treatment of this troublesome and obstinate disease is the evulsion of the diseased nail. The nail should first be divided longitudinally with a pair of strong scissors, and then each half should be separately seized and extracted with a pair of chiropodist's forceps. After the bleeding has ceased, the whole ulcerated surface should be lightly touched with nitric acid, after which cold water dressings should be applied. At intervals of forty-eight hours, the surface may be brushed over with nitrate of silver, or with the compound solution of bromine. The cold water dressings may be continued with advantage until the parts are restored to a sound condition, or a lotion may be employed of liquor sodæ chlorinat. diluted with eight parts of water. When a toe is the seat of the disease, the lower extremity should be kept in a horizontal position. Under the treatment which I have recommended the disease has generally been cured within a few weeks. When onychia has occurred from constitutional causes, appropriate internal remedies should be administered.

Onyxis, or inverted toe-nail, is a disease which affects almost exclusively the great toe. It presents the character of an inflamed ulcer, involving the dorsal integument of the toe, on one side of the nail, the angle formed by the junction of the side of the nail with its anterior extremity, being imbedded in the substance of the inflamed and ulcerated skin, and thus keeping up the irritation, and preventing the ulcer from healing. This painful and troublesome disease is occasioned partly by an original malformation of the nail, partly by wearing a shoe or boot too narrow for the foot, and partly by cutting the nail too short at its angle, so that it is overlapped by the integument. In order that the patient should enjoy any degree of comfort, and that a chance should be afforded for the cure of the disease, it is indispensable that the sole of the boot or shoe should be sufficiently wide to prevent any injurious lateral pressure. In cases where the disease is of short duration, and of moderate severity, relief may be afforded by lifting up the angle of the nail with the handle of a scalpel, and interposing a small piece of soft linen rag between the nail and the skin. Benefit will also be derived from cutting the free extremity of the nail, so as to present a concave line, the middle of the nail being cut shorter than the angles. The nail may also be soaked in warm water, and scraped with glass, so as to make it thin and flexible. When relief is not afforded by these means the surgeon may avail himself of the plan of treatment suggested by Dr. J. P. Batchelder, of this city. This plan consists in cutting a longitudinal groove in the nail at a short distance from its inverted edge, the groove extending nearly, but not quite, through the thickness of the nail, and then lifting up the edge of the nail, and interposing a linen rag between it and the skin. By this means a change in the direction of the nail is effected, sometimes leading to a radical cure.

In the most severe and obstinate cases of the disease, evulsion of the nail becomes necessary. The nail should first be scraped in the middle, and then divided longitudinally with scissors, after which the two lateral portions should be extracted with a chiropodist's forceps. The operation is sometimes performed by extracting only the lateral half of the nail, corresponding with the side on which the inversion existed. I am satisfied, from personal observation, that the relief afforded in this way is not as complete as when both lateral portions of the nail are extracted, and that the new nail which afterwards grows is not as perfect in shape. After removing the nail, the foot should be kept elevated, and cold water dressings constantly applied. As the new nail begins to grow, care should be taken to prevent its margin from being imbedded in the skin, and, as soon as practicable, the margin should be elevated, and a soft rag interposed between it and the integument.

Hyponychial or Subungual Exostosis.—This is a bony excrescence from the dorsal surface of the last phalanx of the toe, where it is covered by the nail. In the great majority of cases, it occurs on the great toe, but it is occasionally seen on one of the smaller toes. It is ordinarily a result of a contusion of the affected toe. The patient complains of pain beneath the toe-nail, and, when the part is examined, the nail is found to be abnormally prominent. The morbid growth is frequently situated so far forward that it elevates the free extremity of the nail, and gives it an abnormal direction. The pain is chiefly occasioned by the resistance which the dense structure of the nail opposes to the growth of the tumor. It constitutes a serious annoyance to the patient, and greatly interferes with his comfort in standing and walking. The indication of treatment is to remove the morbid growth in such a manner as to prevent its reproduction. The nail must first be divided longitudinally with scissors, and the lateral halves extracted with forceps. The bony tumor may then be removed with a chisel or gouge, care being taken to carry the excision below the normal level of the dorsal surface of the phalanx; or, a stratum of the phalanx, including the base of the tumor, may be removed by means of a metacarpal saw. The wound may then be left to granulate and cicatrize. During the healing process the limb should be kept in a horizontal or slightly elevated position.

Dr. Minot, in the *Boston Medical and Surgical Journal*, gives the following case. A child three years old sickened December 21st; an eruption, supposed to be that of measles, appeared on the 25th. The diagnosis at first was a little doubtful, owing to the eruption being complicated by urticaria for two days. After this time, it had a perfectly normal appearance, and was attended by catarrh and other general symptoms of measles. A companion, who saw him early in the disease, was attacked with measles exactly a fortnight afterwards. A sister of the first patient and a young lady visiting in the family also took the disease at intervals of a few weeks. On February 3d, after a few days' indisposition, the eruption reappeared on the first patient, and went through its course in the usual manner. The interval between the attacks was six weeks. Singularly enough, of the three who took the disease from this patient, two had had the disease before.

Progress of Medical Science.

Action of Chloroform on the System.—Most of those who have carefully studied the effects of chloroform when administered in vapor to animals are of opinion that the first effect of the anæsthetic is excitant, and that this is followed by a sedative effect. This, however, is not the conclusion of M. P. Bert, who has presented a memoir to the French Academy on the action of chloroform as an anæsthetic. From his experiments on dogs and other mammals, M. Bert concludes that the excitant action of chloroform is a false one, and that it does not depend on any systemic effect of the vapor. He asserts that the excitant action is due to the effect of the vapor on the mucous coverings of the eyes, nose, mouth, and glottis: the chloroform irritates these surfaces, and produces the movements generally observed, and usually attributed to the effect of the *absorbed* vapor. It proof of this, M. Bert cites the following experiment: "I opened the trachea of a dog, and inserted into it a small glass tube connected with an inhaling apparatus. Into the latter I put some pieces of wool steeped in chloroform. Anæsthesia soon took place, but the animal slept tranquilly, and there was no period of excitation."—*Lancet.*

Cysticercus Cellulosæ in the Anterior Chamber of the Eye.—Oct. 10, 1866, Mrs. A. G., 28, sought the advice of Prof. *Förster*, of Breslau, on account of her left eye. About fourteen days before, she discovered that objects seen by that eye, in direct vision, seemed as if covered by a veil or cloud; there had never been any pain or redness in the eye; her husband saw a whitish round spot on the lower portion of the cornea, hence she came to Dr. Förster. In the anterior chamber a vesicle is seen which is immediately recognised as a cysticercus cellulosæ; it is about two millimetres in diameter; of a grayish white color; very translucent, and is adherent to the lower portion of the iris by a very fine pedicle (stiel). This pedicle is so short as scarcely to deserve the name. It appears rather like a point of the vesicle which is adherent to the iris. On motion of the eye, the vesicle floats about somewhat, though hindered by its connexion with the iris. The iris is normal in color, and in its secretion. A weak solution of atropine dropped into the eye shows that there is no adherence of the iris to the capsule of the lens, and presses the vesicle near to the lower corneal cords. There are changes in the form of the vesicle, which occur somewhat spasmodically. It then loses its round contour, becomes irregularly polygonal, and seen by a magnifying glass, the vesicle seems to contract towards a central point. A milk-white, almost opaque spot, represents the position of the head and neck. The eye is free from pain; free from irritation and injection; the cornea is fully transparent, except in two extremely small points lying on the posterior corneal surface; the media are clear, direct vision is unimpaired, the visual field is a little cloudy below. The patient in other respects is well.

Oct. 13.—After the effect of the atropine had passed away, the extraction of the cysticercus was done by Prof. Förster. A cataract-knife was introduced into the anterior chamber through the cornea, passing the knife under the vesicle. As the aqueous humor escaped, the peripheral portion of the iris bulged forward, and with gentle stroking of the cornea with a Daviel's spoon, from above downwards, the cysticercus ran out, having been loosened from its adherence to the iris without further instrumental aid. The prolapsed iris was cut off.

On the 9th day after the operation patient went home. The cysticercus lived for some time in tepid water, making distinct movements, but the head could not be caused to protrude by pressure. This is the first case of cysticercus in the anterior chamber which has been seen by Professor Förster among 30,000 eye cases observed by him.—*Dr. Krüger. Zehender's Journal*, V. Yahrgang; März und April, 1867.

The Enucleation of Nævus.—Mr. Thomas P. Teale, Jr., read a paper before the Royal Medical and Chirurgical Society on this subject. He advocated two principles which have received, as yet, little attention from surgical writers. The first is, that there exists in most cases of large nævus a distinct capsule which will enable the surgeon to enucleate the tumor without cutting wide of the disease, and thereby endangering large blood-vessels or nerves. Mr. Paget advanced this principle in *Holmes' Surgery*, vol. i., p. 498 (three cases are there adduced as proofs of it). The second principle is, that when a portion of skin covering a nævus is involved in the disease, it is not necessary to sacrifice such diseased skin, as it may be dissected off the tumor, and being retained as a cover to the wound, will gradually regain its natural appearance. This slow change is brought about by the gradual contraction of the internal cicatrix, by which the nævoid skin becomes united to the wound which it covers. It is an instance of the value of the designed production of atrophy by means of cicatrix.

Mr. Curling remarked on the general dread of using the knife in such cases, as there have been some deaths from hæmorrhage. Mr. Teale has adopted the procedure mentioned in the paper in some very formidable cases; but it was not suitable to all.

Mr. Prescott Hewett thought surgeons were too prone to early operation, as nævi will often disappear in time.

Mr. Birkett stated that in one case where there were twenty or more nævi, all were now gone.—*Medical Times and Gazette.*

The Value of Chloroform.—As we have given place recently to the opinions of Prof. Petrequin on the respective value of ether and chloroform to produce anæsthesia, it is but just that we do the same for the contrary views of Prof. Sedillot; the former represents the Medical School of Lyons, and the latter that of Strasbourg. Sedillot has, like many surgeons, given up long ago the use of ether for that of chloroform; for this his practical reasons are very likely stronger and more cohesive than his theoretical ones, which are few, but rather discordant. He literally says: 1st. Every time we have recourse to chloroform the question is of life or death. 2d. Chloroform is an art which requires an attention of every instant, and great skill and experience. 3d. Chloroform perfectly pure and properly applied never kills. But his remarks on certain points of application deserve better attention. When using chloroform, 1st. Let us avoid those deep inspirations as they are sometimes produced after a cough, or a momentary stop in the breathing process consequent upon laryngeal spasm—a single inspiration of the kind may be fatal. 2d. The apparent regularity of the respiratory movements is no proof that air penetrates into the chest. The glottis may be shut, and we must always ascertain the reality of the noise that is produced by the passing of the air through the glottis. 3rd. The cough shows the persistency of irritability of the nerves and muscles which could be allayed by continuing to use the anæsthetic agent. Vomitings are also proofs of commencing anæsthesia, and are stopped by renewed inhalations. 4th. It would be dangerous to try to completely paralyze the muscles in view of facilitating the reduction of luxations,

because their mobility is increased with greater energy as soon as extension is practised. In ophthalmic operations the same remark obtains. 5th. Paralysis of the tongue must be avoided because it falls on the larynx, rendering asphyxia imminent. 6th. Among the causes for suspending momentarily the inhalations, are: the quantity of chloroform inhaled, the coming of a period of excitement, mutism, insensibility to contact, reversion of the globe of the eye, incipient resolution of the limbs.

Practically acknowledging the difficulties which surround chloroformization, Dr. Sedillot advises the use of ether by inexperienced hands, and confesses that all the Strasbourg surgeons have recourse to the skill of Dr. Elser to produce anæsthesia in their surgical practice; Elser having operated for the learned faculty 14,000 times, meeting with no accident, and giving the greatest security to the operators who have recourse to his skill.

Thus Sedillot avoids the question of principle, and finds for his opinion the refuge of the extraordinary skill of Dr. Elser. Let us hope there will be, if possible, a few more Elsers, or a better and wide-spread knowledge of chloroformization.

Inoculability of Tubercle.—In the *Gazette Hebdomadaire* we have a continuation of N. Villeman's researches as to the inoculability of tubercle. In rabbits, he has again and again succeeded in reproducing it in this manner, not only when taken from the human subject, but still more rapidly when taken from the cow; further, the tubercular matter thus produced in one rabbit could be, in like manner, transmitted to another, in the same way as syphilis.—*Medical Times and Gazette.—Richmond Medical Journal.*

Application of Collodion in Cholera (*L'Union Médicale*).—Dr. Drouet, of La Grand-Montrougue, maintains that the external application of collodion will arrest the premonitory diarrhœa, and afford an excellent means of restoring warmth in confirmed cholera. He uses a mixture of collodion 6 parts, castor oil 1 part, smeared over the abdomen, and covered with cotton wool. The evaporation of the ether at first causes a sensation of cold, but in a few minutes this is followed by a feeling of warmth, which increases in intensity, without, however, becoming so intense as to cause distress. This application, he says, will certainly arrest the progress of the disease, if used during the first hours of the attack, and provided it be not of an extremely violent nature.—*N. Y. Medical Journal.*

A New Form of Suture.—Dr. Albert H. Hoy, of Racine, Wis., in speaking of the rubber suture, says: "We have repeatedly used a suture to which, not knowing of its being mentioned in any treatise on surgery, we desire to call the attention of the profession, trusting they will find that it meets the indications of a good suture, viz.: 1st, adaptation of the edges of the wound; 2d, producing little irritation; 3d, easily applied. In using it, the following things are required: 1st, a paper of ladies' sewing needles, the points of which, for one third their length, have been heated in a lamp and curved like a surgeon's needle; No. 4 is the best size; 2d, some rubber elastic bands, cut into inch lengths; that having a width of $\frac{1}{16}$ of an inch will be found most generally useful; 3d, a pair of small pliers and wire-cutters. To introduce the suture, one of the needles is taken firmly by the eye with the pliers, and a piece of the rubber band is strung on, near one of its ends, and the needle, thus armed, is thrust through the edges of the wound, thus holding them together. The free end of the rubber band is then strung over the point of the needle, care being taken to give the band just sufficient tension to hold the lips of the wound snugly together. The points of the needles are then snipped off with the cutters, and the suture is complete. The above suture is highly recommeded in harelip and other plastic operations, where speedy union of the cut surfaces is of the greatest importance."—*Chicago Journal.*

Ruptured Heart; Insufficiency of the Aortic Valve; Hypertrophy and Dilatation.—In the *Boston Medical and Surgical Journal*, Dr. Shattuck relates the following case. A man aged 50, previously in good health, after sleeping in a cold, damp room, awoke in the morning with pain in his chest, a frequent, loose cough with frothy expectorations, streaked with blood. These symptoms continued, with considerable dyspnœa and pain on taking a long breath. The first sound of the heart was loud and accentuated, followed by a short murmur. There were no râles; diminished resonance and bronchial inspiration and respiration in right supra-spinous fossa. Resonance marked over the front on each side of the chest, and loud respiration under both clavicles, and even in cardiac region. In the course of ten days there had been much improvement, but afterwards suffered greatly from asthmatic breathing; while sibilant and sonorous râles were heard all over the chest, but more distinct in front. Subsequently the dyspnœa became extreme; he had profuse sweats and sometimes delirium. The diastolic murmur became louder over the aortic than over the pulmonic valves. About two months after being attacked "he had an exceedingly severe paroxysm of dyspnœa, and while tossing about on the bed, suddenly sprang up, threw himself back, and after gasping for a moment, expired." An autopsy revealed the following: pleura of right lung universally adherent to costal pleura and the diaphragm. In left pleural cavity were found twenty-eight ounces of reddish, straw-colored serum, and the lining membrane of bronchial tubes of a deep red color. Left lung œdematous in upper lobe, and right lung somewhat œdematous. The pericardium contained three ounces of dark fluid blood. Several white patches seen on external surface of heart. Nearly over the septum between the ventricles, to the right of the coronary vein, on the anterior surface of the heart, and one inch and an eighth from the apex, is seen a rent, looking like an incised wound, running in a direction parallel with the septum. The rent gaped but slightly, was five lines long, and communicated freely with the cavity of the right ventricle. One of the aortic valves had its free edge contracted, and another was thickened by warty deposits. The mitral valve was healthy. The ascending aorta was dilated, and the upper two and a half inches of the thoracic aorta were much dilated, and the artery much thickened by atheromatous deposits.

Poisoning by Strychnine.—Dr. John Bartlett, formerly of Chicago, strongly recommends common salt as a curative of strychnine poisoning. He reports as many as twenty experiments on dogs, in which violent symptoms following large doses of strychnia ceased after emesis, induced by drenching the animals with water, holding in solution several handfuls of salt.—*Chicago Medical Journal.*

Hypodermic Injections.—They will be found invaluable in relieving pain and nervous irritability in all surgical accidents. It has also been found to prolong the anæsthesia from chloroform. I now inject one-quarter to one-half grain of morphine, when I expect my patient to be continued under chloroform for a length of time. The attention of the profession is respectfully called to this fact.—Wm. A. Greene, M.D., in the *Atlanta Medical and Surgical Journal.*

THE UTERINE ELEMENT IN PRACTICE.

THE advances which have been of late years made in the department of uterine pathology have not been without their effects upon general practice. The brilliant success which has associated itself with the labors of a few pioneers in this branch, has thrown open the lists to very many aspiring imitators, a class which has notably increased within the past few years. So great indeed has been this infusion of the uterine element into practice, that it is considered one of the necessary accomplishments of almost every general practitioner to make a vaginal examination of every female who falls into his hands, and discover as the inevitable result of such a procedure, some more or less important uterine disease. If any female is the possessor of any anomalous symptoms, if she escapes nowadays without a *careful* examination with the speculum, a few leeches to the os, a cauterization of the cervix, a pessary, a sponge tent, or a sea-tangle bougie, she is exceedingly fortunate.

To any one conversant with current medical literature, the fact is a very patent one that uterine diseases, if not on the increase, are certainly claimed to be very prevalent. This may be in a measure accounted for by the progress which has recently been made in the more thorough study of such affections, and the more satisfactory means at our command for arriving at a correct diagnosis; but we are compelled, from the circumstances of the case, to go a step further in assigning the reason for this so-called remarkable increase of uterine affections, and assume that the vast majority of them exist only in the imagination of the attending physician. Unfortunately for the cause of science, diseases of the uterus are as fashionable with physicians as with their nervous and hardly less senseless patients. Almost every third female invalid comes to the conclusion that she has that traditional, and as she thinks expressive complaint, "falling of the womb," and her family physician rarely fails to discover some slight enlargement of the cervix, a ring of congestion around the os, or a trifling amount of displacement! The usual routine treatment is instituted, the cervix is either melted down with potassa fusa or nitrate of silver, and then an interesting little contrivance in the shape of a pessary—an instrument, the oft-demonstrated exponent of ignorance and hobbyism—is applied, and the indications of the case are supposed to be met.

The testimony of all the experts in this branch is to the effect that the prevalence of uterine troubles is more than overestimated, and these assertions are based upon the fact, that very few of all the patients sent them have anything in the shape of uterine abnormality whatever. But as this statement only refers to those which are supposed to be desperate cases, what can be said concerning the trivial ones which are treated in the routine of a general family practice! Can there be much of error in the assertion that much is done for the large number of supposed sufferers which is not only utterly useless, but positively detrimental to the well-being of one of the most important organs in the economy?

It is perfectly natural for the uterine specialist to meet with any number of cases that are of comparative rarity, but hardly possible for every general practitioner to be equally favored; there is a certain law which governs the proportion of remarkable cases which cannot be ignored even by those who court uterine practice, while the plea of a correct diagnosis in every case, is in itself evidence of a transcendentalism, that is, to say the least, absurd.

Aside from the assumed prevalence of diseases of the uterus, there is an excuse for an extensive practice in this branch, in that it is so remunerative; and it is pretty generally understood that a gentleman skilled in introducing speculums and diagnosticating obscure womb diseases, has the strongest possible recommendations for business among that large class of would-be sufferers—the women. In this connexion we may remark that we recently heard it asserted by a gentleman long engaged in general practice, and who is supposed to be acquainted with all its requirements, that there were more fees collected for the treatment of diseases of the uterus, that were not fairly earned, than for those of any other organ or sets of organs in the body. No one acquainted with the merits of the case as he was could fail to come to the same conclusion.

It is legitimate enough, on general principles, to extend the circle of any one's practice, and if there is a demand for services to the uterus it must not be neglected any more than to the eye, the throat, the ear, the bladder, or the anus; but the significant question here obtrudes itself—Is the profession, by its treatment of these cases, doing its best, not only to lessen the suffering of uterine patients, but to persuade them at the same time that their ills are more imaginary than real? If the latter part of their duty is not conscientiously performed, the only excuse for indiscriminately cauterizing, incising, leeching, and "*supporting*" a comparatively inoffensive organ, is to be found in a disgraceful and therefore culpable ignorance of the fundamental doctrines of uterology.

This want of knowledge is the only would-be uterine pathologist's excuse, and its worthlessness is apparent, when he has within his grasp all the improvements which the labors of his more practical and scientific brethren have placed before him. He pretends to imitate them, when in reality he has become so poisoned with routine, that he is ten years behind the age. Even allowing a wide margin for all exaggeration as to the increased prevalence of the diseases, there is no reason why there will not be enough to claim the serious attention of every general practitioner; but in the name of science and humanity, let them be treated intelligently, let there be more exact knowledge and less empiricism, more brains and fewer instruments.

We have an announcement from an authoritative source, to the effect that it is the intention of the Medical Staff of Bellevue Hospital to issue a yearly volume of interesting cases occurring in that institution. This, if the project is carried out, will be the first instance within our knowledge in this country of collecting in an endurable form the valuable material of a large charity. The example of the faculty of that hospital deserves to be followed by other and older institutions throughout the country. There are not a few of these, among which may be prominently mentioned the New York Hospital, which has volumes of manuscript cases, and for the want of a suitable vehicle for their publication, they are hidden from all save those favored few who have access to the library. Many of the very interesting, not to say important cases, never have seen, or will see, the light, except some such means are taken to present them to the profession. Except for the occasional appearance of an isolated report of an operation or two by some members of the House Staff, or the occasional mentioning of a case to a society, the medical public would hardly be aware of the existence of the hospital. The same may be said of other similar institutions not very far off. It occurs to us that it would be feasible, in carrying out the plan of such a publication, to appoint clinical clerks whose duties should be to write up all the cases for publication, and submit the same to each interested party for revision, the corps being under the direction of a competent person, whose duty it should be to group and arrange them as would best suit the purposes of such a volume. For the faithful and acceptable performance of such duties a liberal salary should be allowed to all concerned, to stimulate industry and infuse a proper interest in the work. The material of Bellevue is ample, and there are plenty of men who would, for a consideration, be willing to perform the necessary labor; and if the project fails it will only be for the lack of a suitable appropriation to carry it out. The profession will undoubtedly gladly receive the volume, and the amount of pecuniary returns which the projectors will realize will be sufficiently ample to enable them to meet all their necessary liabilities.

Reviews.

INSANITY IN ITS MEDICO-LEGAL RELATIONS. Opinion relative to the Testamentary Capacity of the late James C. Johnston, of Chowan County, S. C. By W. A. HAMMOND, M.D., etc. New York: Baker, Voorhees & Co. 1866. 8vo., pp. 72.

THIS is an interesting, suggestive, and instructive pamphlet, treating upon several important points connected with moral insanity, the principal of which is that referring to the non-existence of any lucid interval in the monomaniac. Numerous interesting cases are cited by the author to prove his position, and the arguments which he offers are convincing. Every physician who may wish to prepare himself to testify in a court of law upon the question at issue, should read this little work, and profit by the facts which are presented in it. It is written in the usual elegant and attractive style of this well known and talented author.

DIE CHRONISCHEN KEHLKOPFES-KRANKHEITEN, mit specieller Rücksicht auf Laryngoskopische Diagnostik und locale Therapie, von DR. ADELBERT TOBOLD, Sanitätsrath und Docent der Berliner Universitat. (Chronic Diseases of the Larynx, with Special Reference to Laryngoscopic Diagnosis, by DR. ADELBERT TOBOLD, Lecturer in the University of Berlin.)

THERE are not a few who, having heard of laryngoscopy only as an interesting and beautiful wonder, suppose that at best it is merely a scientific plaything, which can have no very radical influence on the therapeutics of the affection that it aids us to diagnosticate. If we mistake not, this is the opinion, or at least the impression, of the great majority of the profession. It would be a great benefit, therefore, if either a translation of this work of Dr. Tobold, or some original work in our own tongue, could be introduced into general professional circulation.

The short period of a little more than eight years which has elapsed since the discovery of the laryngoscope has been marked by great activity in the literature of that subject, and yet until the recent appearance of this work of Dr. Tobold there was scarcely any treatise of much length devoted exclusively to chronic diseases of the throat. If we except a few brochures treating of some special affections, nearly all the treatises on this subject, excepting the very unsatisfactory work of Dr. Gibbs, are chiefly occupied with explanations of the use of the laryngoscope and the history of its discovery. Dr. Tobold assumes that his readers are familiar with the instruments employed, and after giving a few hints in regard to the possibility of always making a successful examination with them, he devotes the greater portion of the work to the pathology, ætiology, prognosis, and therapeutics of laryngeal diseases.

The chapters on new formations ought to convince the most sceptical that the discovery of the laryngoscope has introduced an era in medicine.

The author has very little faith in inhalations, at least for the portion of the mucous membrane that lies above the vocal cords. We think that in this particular Dr. Tobold does not sufficiently recognise the necessity, that is everywhere laid upon physicians, of consulting the feelings of their patients. Those who will not endure the sponging and injecting with strong solutions of nitrate of silver, alum, or sulphate of zinc, that he finds so efficacious, may be perfectly willing to inhale the same substances, and so put themselves in the way of cure, though the course of treatment may be more protracted than under the heroic system.

Certainly the use of medicated inhalations is now

advocated by higher authority than that of charlatans. The ideas advanced on the relation of laryngeal ulceration to tubercular deposits in the lungs should be thoroughly considered by every practitioner. If it be true, as the author asserts, that "laryngeal tuberculosis is exclusively a secondary product of lung tuberculosis," then the time has already come when no one should presume to be authority on diseases of the lungs who is not familiar with the use of the laryngoscope; for by as much as the evidence of the eye is more reliable than that of the ear in medical study, by so much must the inspection of the larynx be a more satisfactory aid in the diagnosis of certain stages of lung affections than the auscultation of the chest. Original and interesting as is this work of Dr. Tobold, we think that, had a detailed exhibition of a limited number of cases been added, its value would have been much increased.

Reports of Societies.

N. Y. PATHOLOGICAL SOCIETY.

STATED MEETING, MARCH 27, 1867.

DR. H. B. SANDS, President, in the Chair.

DR. ROGERS next made some allusion to the case of Fallopian pregnancy, presented by Dr. Finnell at the last meeting, more especially in connexion with the practicability of performing gastrotomy with the view of arresting the hæmorrhage. He had made it his business to inquire into all the circumstances of the case, and had been enabled to arrive at the conclusion, that, had the patient been seen, in the early part of her illness, by an intelligent practitioner, her life might have been saved. It may be remarked, in passing, that Dr. Finnell had no previous knowledge of the case before he was called upon to make the autopsy. Dr. Rogers ascertained that in addition to the symptoms which occurred ten days before death, the patient had been ill for some time, something like six weeks, during which period she had supposed herself pregnant. She had been unable to leave her bed for a period of three weeks. At that time she thought that she was about to abort, and was said to have had a sanguineous discharge one week before her pains came on. The remarkable circumstance was that she was ill enough to frighten her neighbors for a period of a whole week, and yet no physician was sent for. The pains in the afternoon of the first day subsided after a time, but subsequently it was noticed by her attendants, her daughter and a neighboring woman, that her belly became much enlarged, was very soft, and seemed, as they expressed it, to be filled with water. This was a very important symptom for any physician who might have seen the case. The other important point had reference to the situation of bleeding. The opening was a very small one, not larger than the diameter of a crow-quill. She was seen by a physician about two hours before she died, who pronounced her case one of colic.

In reference to the remark made by Dr. Finnell in regard to the chance of saving the woman by an operation, Dr. R. remarked, that the more he thought of the case the more he became convinced that her life might have been saved. If she had been seen the first day there could have been no danger of a wrong diagnosis.

CANCEROUS TESTIS.

DR. MARKOE presented a cancerous testis, and remarked upon it as follows:

I have a specimen which I merely present to the Society as a fact to which I hope hereafter to add a history; a fact, which is somewhat interesting from the rarity of its occurrence, and the pathological interest which attaches to the certainty and rapidity of the reproduction of this disease. A child, between two and three years of age, received some six months before I saw it an injury of the left testicle. The organ enlarged, gave a great deal of pain and distress for a certain time, and then subsided. From that time the testicle gradually increased in size, without a great deal of pain, or without any indication of inflammatory action, until the time at which it presented itself to me. At that time, now about two weeks ago, the testicle had attained the size of an orange; the scrotum was red; the swelling was somewhat pyriform, hanging very low as though dragging upon the cord; the cord was rather slender, and free from any contamination; one-half of the testicle was of a dark red, and the other was of a darker color and purple. The only question that could suggest itself at first was, that the mischief might have the character of an hæmatocele. I introduced an exploring needle, which was followed by the exudation of a serous fluid, and then by blood. I then determined to extirpate it, which I did immediately, and here it is. On examination the evidences were very satisfactory of its malignant character. Its gross appearance is very characteristic of soft cancer.

In conclusion he referred to a similar case operated upon by Dr. Parker, with a similar result.

DR. F. DELAFIELD, in reply to a question from Dr. Sands in regard to the microscopical character of the diseased mass, stated that it was composed, for the most part, of large round nucleated cells in well formed areolæ, many of the cells being in an advanced stage of fatty degeneration. There were almost no fusiform cells.

DR. SANDS stated that the reason why he asked the question was that, having had occasion to examine the testis removed by Dr. Parker, he had found it to be made up of the fusiform cells peculiar to the fibroplastic tumor. He had considerable difficulty in this examination, on account of the abundance of fatty degeneration present. He remarked that he had consulted Holmes's Surgery on the subject of tumors of the testicle, and had found mention made there of a similar specimen, which had been examined, and found to be fibro-recurrent, but the history of the tumor showed it to be malignant, that is it had a fatal termination by recurrence. Some surprise was expressed in the work referred to, that a tumor having these microscopical characters should have returned.

CYST OF OVARY:—OVARIOTOMY.

DR. J. B. CUTTER presented a specimen of single cyst of the left ovary, which he had removed by operation thirteen days before. The patient was an unmarried lady, twenty-three years of age. The disease had existed five and one-half years. She had been tapped in that time four times, about a year apart. The fluid at each time was albuminous and dark in color. The incision was made in the median line of the abdomen, midway between the umbilicus and pubes, and was four inches in length. There was one adhesion upon the right side of the tumor, which was to omentum. The extent of adhesion was about six inches, the vessels were very large and tortuous, some of them being equal in size to a lead pencil. It was decided, however, to tap the cyst, and remove it. There was another small attachment to the tumor, but its exact character it was not prudent to ascertain. This was tied with a stout silk ligature, and then a clamp was placed upon the omentum, which was divided so close that the cyst was cut into. The pedicle, which was a long, slim one, was next divided, and tied with a double silk ligature. The omentum

was next examined, when it was found that there was hæmorrhage below the point ligatured; the part was then secured again, and the mass beyond the ligature cut off. Each pedicle was included in the wound.

Ether and chloroform were first administered, but not acting well, ether alone was employed. She vomited slightly but once during the administration. After the patient was placed in bed, she complained of some soreness about the wound, and twenty-five drops of McMunn's elixir of opium were ordered. She never suffered from any pain from that time, and the abdomen remained perfectly flat. On the third day in the morning ten drops of McMunn's elixir were again administered with a view of keeping in check the peristaltic action of the bowels. On the tenth day the ligature from the omentum came away. There was suppuration at each pedicle. On the fourth day there was a slight fæcal discharge, and the Mc'Munn's elixir was substituted by tinct. of opium, and no movements took place until the eighth day, when a dose of oil was administered.

In answer to a question from Dr. Rogers, he stated that it was not considered at all dangerous to leave blood in reasonable quantity in the peritoneal cavity.

VESICO-INTESTINAL FISTULA.

Dr. Robert Watts, Jr., presented an interesting specimen of communication of the bladder with the intestinal canal. It was removed from a woman, who was an inmate of the Charity Hospital, on account of phthisis and syphilis. Soon after admission she was seized with diarrhœa, which continued until her death. On two or three occasions she had hæmorrhage from the bowels, but never to any great extent. Last November she, by mistake for Magendie's solution of morphine, took a grain of atropine. This was followed by the symptoms peculiar to poisoning by this alkaloid, viz. extreme dizziness, dryness of the fauces, and extreme dilatation of the pupil. She was treated immediately with an emetic of sulphate of zinc, and the stomach-pump. But although she recovered from the immediate effects of the poison, she had persistent vomiting, being only at times able to retain lime-water and milk, with which she was of necessity constantly fed. During the course of her sickness her urine was examined, and found to contain albumen and casts. There was nothing peculiar about her alvine dejections.

On making the post-mortem, the stomach was found perfectly healthy. The liver was fatty, and the lungs tuberculous. Both kidneys were found the seats of fatty degeneration.

The cavity of the pelvis gave evidences of old peritonitis, and all the organs were found bound together as the result. The rectum was pushed over to the right side, and returning on itself again had formed a large loop, the two ends of which were bound down closely to the bladder, and from each end there was a direct communication with the bladder. The left kidney had two ureters, which ran side by side, and opened at one point by separate orifices in the bladder. The patient had no bladder trouble, nor symptoms of peritonitis during her stay in the hospital. Death was occasioned simply by exhaustion.

The Society then adjourned.

Stated Meeting, April 10, 1867.

Dr. H. B. Sands, President, in the Chair.

FIBRO-PLASTIC TUMOR OF EYE-BALL.

Dr. F. Delafield exhibited a tumor of the eye, which he had removed on the 29th of March from a patient of the N. Y. Eye Infirmary. The patient was 45 years of age, of large frame, and apparently in the enjoyment of perfect health. About three years ago, he first noticed an impairment of the inner half of the field of vision of the right eye. This condition of things grew worse and worse, until finally he lost the sight of that eye altogether. There was at no time that he recollected any symptom of inflammation about the organ to account for the phenomenon, neither had he received any injury to the eye. On the 26th of December, he first presented himself for treatment at the Eye Infirmary; and at that time complained of pain in the eye-ball, and in the forehead over the eye. On examination of the affected organ, the pupil was dilated, the lens opaque, and only the external half of the retina, with two or three blood-vessels upon it, was visible. The conclusion arrived at was, that there was a tumor of the choroid or retina, lifting up the latter. Extirpation of the eye was accordingly advised; but the patient refused to have the operation performed. He was seen on two or three different occasions after this, and was found to be about the same, and then he was lost sight of until the 20th of March last. He then returned to the Infirmary with the story, that, for the previous fourteen days, the pain in the eye and forehead had very much increased—so much so, that he had not been able to obtain any rest day nor night. The pupil was then found still more dilated, the conjunctiva ecchymosed, the eye-ball exceedingly tense, and the retina in any part was no longer to be seen. Consenting to extirpation, the operation was soon after performed. On examination of the organ after removal, the posterior third of the eye was occupied by a tumor springing from the choroid, and detaching the retina, so that the latter was folded together and much atrophied. The mass consisted entirely of fusiform cells, with oval nuclei; and, what was somewhat remarkable for a choroidal tumor, there was no deposit in its substance of pigmentary matter.

SUPERNUMERARY FINGERS.

Dr. Post presented two supernumerary fingers, one from the right and the other from the left hand of a little patient three months old. One of these was possessed of a rudimentary nail. The interest of the case centred in the proof of a remarkable hereditary freak. The mother had a scar upon one of her hands, marking the situation of an amputation of the same finger upon the same side, and had given birth to eight previous children without any blemish; and what seemed more curious was, that her supernumerary finger had a rudimentary nail upon it precisely as the same finger removed from the same hand of her ninth issue.

In answer to a question from Dr. Rogers, he remarked that, in his opinion, this was an illustration of hereditary transmission, which had allowed of a long interval of time to show itself.

RAPID EXFOLIATION OF BONE.—NON-FORMATION OF INVOLUCRUM.

He next exhibited a rather unusual instance of necrosis of the fibula, which he had removed by operation from a boy ten years of age. On New Year's day the patient went out skating. His skate on the affected leg was strapped unusually tight, and interfered with the circulation of the limb, which became very much chilled. On his return home, he experienced considerable pain in the leg, attended with fever and headache: inflammation followed, which was regarded as erysipelatous in character, and was accompanied with much swelling. During the first four days, in addition to the other symptoms, there was pretty active delirium. About February 1st, after leeches had been applied, there was

discharge of matter through one of the bites, and subsequently some scales of bone made their exit. The child was presented to Dr. Post for the first time on the 9th instant. On examination, he discovered two sinuses, one of which was situated an inch above the ankle-joint, and the other about two inches higher. There was no appearance of inflammation above this latter point. The probe introduced, discovered bare bone; and, after enlarging the lower opening, almost the entire fibula was withdrawn with little difficulty. The necrotic tissue was very dense and heavy, and there seemed to have been very little if any tendency to the formation of an involucrum. He regarded the specimen as interesting in relation to the short interval of time which elapsed between the commencement of the attack and the ultimate exfoliation of the bone. Both articular extremities of the fibula were left intact, and were not involved in the diseased action.

Dr. Rogers thought that it was very remarkable that the articular extremities should escape under such circumstances.

Dr Krackowizer, on the contrary, stated that it was no uncommon thing to have the disease in growing persons arrested at those points. In fact, it was the rule rather than the exception. The true point of interest was in the exfoliation of so large a portion of the fibula under any circumstances, as the death of that bone was almost always partial and confined to mere shells, even where the tibia at the same time was almost entirely destroyed.

Dr. Sands asked if the periosteum was removed with the dead bone, and was answered in the negative.

Dr. Rogers did not think that there would be likely to be a regeneration of the bone, as there was at the time of the operation no disposition to the formation of an involucrum.

Dr. Post was of the opinion that there had been no time for the proper formation of the involucrum, and that eventually new bone would be produced to occupy the place now left vacant.

Dr. Sands alluded to a specimen of necrosis of the tibia, which he had presented on behalf of a surgeon of Halifax In that instance, the operation was of necessity performed so near the initiation of the disease, that the periosteum was found so firmly attached to portions of the dead bone, that it was removed with it. After the operation, there was such a feeble attempt at reproduction of bone, that the limb was finally declared useless, and was subsequently removed. In that case, the time which elapsed between the receipt of the injury and operation was much longer than in Dr. Post's patient. There was, of course, no attempt at the formation of involucrum; still, he believed that, could the periosteum have been left, new bone would in time have taken the place of the osseous tissue removed. He was inclined to concur with Dr. Post that, in the case presented by that gentleman, the prognosis was good for the ultimate regeneration of the fibula.

DOUBLE SCIRRHUS OF MAMMÆ.

Dr. Post next presented two specimens of scirrhus of the breast. One of the specimens removed from a patient, sixty years of age, was remarkable for its situation, it being confined to the inner side of the organ, near its sternal margin. The other specimen, taken from a female, forty years of age, showed a dissemination of the disease throughout the whole breast, and presented some peculiar microscopical characters, which are thus described by Dr. Lewis, the gentleman who examined the mass.

Both tumors are specimens of scirrhous cancer—that one which lay near the median line being specially interesting; first, because it lay at the inner margin of the mamma, the portion least frequently invaded by carcinoma; and, secondly, because, while to the naked eye its boundary appears very well marked, under the microscope it was clearly very indefinite, the signs of cancerous infiltration being only less manifest beyond than within the apparent boundary; that is, the stroma consists of the nominal fibro-cellular tissue of the part, changed in the centre of the tumor by the substitution of elongated fibroid, nucleated cells for the fibrous columns, having the interspaces densely filled with various cell elements; so that, in this portion of the tumor, the outline of the individual cells could not be distinguished, only a vast number of nuclei, with bands of fibroid cells running in various directions; but beyond the apparent limit these nuclei were fewer in number, and became less and less numerous, until scarcely a cell was to be seen in the areolar spaces.

The cancer-cells, as seen in the "cancer juice" and the marginal portions of the growth, were spindle-shaped, oval, pyriform, large, and small, and some of the former possessed two or three nuclei.

This tumor was hardest at its central portion; the second was fully as hard and dense near the surface at and in its centre.

Upon pressing this second mamma a thick milky fluid escaped from the nipple, which was also found upon making a deep section through the diseased mass. Under the microscope this was found to consist of multitudes of oil globules, measuring from $\frac{1}{6000}$ to $\frac{1}{2000}$ of an inch, and of larger corpuscles, which may have been colostrum corpuscles, or the exudation corpuscles (granule corpus. of Virchow), measuring from $\frac{1}{1000}$ to $\frac{1}{250}$ of an inch.

The fluid scraped from the cut surface of this specimen contained various forms of cells, long nucleated fibroid cells, small, oval, or irregularly shaped, and spindle-shaped cells. Some of the larger of the ovoid or irregularly-formed, contained several nuclei.

The stroma of this tumor was not investigated.

HAIR-PIN IN BLADDER OF A FEMALE.

Dr. Weir exhibited a specimen of calcareous deposit upon a hair-pin. The body was introduced into the bladder of a single female, æt. 28, as she says by accident, but probably either by design or *mistake*. It remained there until the first of February, she having entered St. Luke's Hospital at that time for the purpose of treatment. Before being sounded, in one of her frequent acts of micturition she experienced more than her usual amount of pain and inconvenience, and in the course of eight hours afterwards, the hair-pin passed with the bent end forwards, she completing the removal with her fingers. The incrustation was almost entirely confined to the middle portions of the arms of the pin, the looped extremity and the free ends being free. The weight of the deposit was 29 grains.

Some discussion took place in regard to the reason for the peculiar situation of the deposit upon the pin, but nothing satisfactory was arrived at.

[Might it not be possible that the pin had previously been legitimately used in the hair, thus becoming eroded in the middle portion of its arms, and this roughened surface afterwards inviting the deposit of calcareous matter when the instrument found its way into the bladder ?]

OVARIAN CYST:—OVARIOTOMY.

Dr. Cutter next presented a specimen of ovarian cyst, removed by ovariotomy from a patient two days before. She was 60 years of age, and first discovered the tumor 18 years ago. The tumor grew very slowly for the first dozen years, but subsequently increased in

size with great rapidity, interfering with the circulation of the lower extremities. Two or three years ago she had been tapped, and 30 or 40 pounds removed, and nine months after, the same operation was repeated, and about the same quantity of fluid evacuated, but of thinner consistency. In the course of six months after, was tapped twice more, each successive time the fluid being thinner than before. In consequence of exhaustion and troublesome obstruction to the circulation, she clamored for an operation, and her request was acceded to. An incision, three or four inches in length, was made in the median line of the abdomen, and a few trivial adhesions having been discovered, the wound was afterwards enlarged. The adhesions were then broken up with the hand, and the contents of the sac evacuated. In attempting to remove the sac there were found three or four adhesions to the omentum, at different points, and one to the vermiform appendix, about its middle; this latter was tied. The pedicle was as broad as the two hands, and occupied nearly the whole of the right broad ligament. It was tied in halves, by double silk ligatures, and no hæmorrhage whatever followed. The patient was doing well up to the time of reporting the case. In making the second cut into the abdominal wall, the scissors was used instead of the knife, and there was noticed a marked difference in the amount of hæmorrhage, the latter instrument seeming to be the preferable one.

Dr. Howard stated that he had seen five cases operated upon by Baker Brown, in which the pedicle was severed by actual cautery. In none of these was there any subsequent hæmorrhage, notwithstanding that in one the pedicle was quite broad.

Dr. Cutter remarked that it was the general belief that cases operated upon in that manner were ordinarily followed by secondary hæmorrhage.

THE PATHOLOGY OF "HOUSE-MAIDS' KNEE."

Dr. Markoe presented an enlarged bursa, removed from the right knee-joint of a middle-aged woman. It had been gradually increasing in size for a period of four or five years, and no cause was assigned for its appearance. The walls of the sac were remarkably thick, but the evidences of the existence of a fluid in its interior were sufficiently strong to make the diagnosis easy. The operation for its removal promised to be equally easy and simple. On cutting down upon the mass it was observed that there was no line of demarcation, and its removal was only accomplished by a rather tedious dissection through a very close and firm fibro-cellular tissue. At one point it was impossible to separate the tumor from the external layers of the aponeurosis of the leg, and the operation was only completed by cutting through a broad portion of this fascia. He remarked that Errichson had alluded to this incorporation of the walls of the sac with the aponeurosis referred to, and thought it was a fact to be borne in mind by younger surgeons who may be called upon to extirpate such growths.

The inner wall of the tumor had a flocculent mass attached to it, while the contents of the sac were very thick and semi-gelatinous in appearance. In connexion with the specimen it became an interesting question as to what was the origin of these tumors—were they natural, in the first instance, or acquired? He was inclined to the belief that no bursa existed over the ligamentum patellæ or patella itself, in the natural condition of the parts, as it was not found in young subjects and in many adults. In confirmation of this latter statement he remarked, that Prof. Watts had given attention to this very matter some years ago, and had looked over all the subjects in the dissecting-room for one season, and had not succeeded in finding a single one of the bursæ.

Dr. Post said that he had occasion to remove three cysts in that situation. In all there was considerable difficulty attending their enucleation.

In answer to a question from Dr. Sands, Dr. Markoe stated that the bursæ were most prominent over the tubercle of the tibia.

Dr. Post, as an argument in favor of the original existence of a bursa in that locality, stated, that he had met with an acute abscess completely confined to those limits.

Dr. Finnell presented a large pendulous cutaneous tumor, removed from the inner aspect of the arm of an old lady who had carried it for ten years. It was removed by simply severing a pedicle three inches long and an inch thick.

Dr. Allin, as one of the committee appointed to report upon the enlarged spleen presented by him at the previous meeting, stated that the organ was found, on microscopical examination, the seat of simple hypertrophy.

The Society then went into executive session.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Fourth Annual Meeting.

The Society met at the Cataract House, Niagara Falls, Tuesday, June 11, 1867, at 12 M. In the absence of the President, Dr. Edward Delafield, of New York, the Vice-President, Dr. Henry W. Williams of Boston, called the meeting to order, and made a few congratulatory remarks, in the course of which he stated that it was believed that the Society had done good, in increasing the respect felt for special labors in the field of Medicine. The following members were found to be present:

Boston.—Drs. Henry W. Williams, Haskett Derby, B. Joy Jeffries; *New York.*—C. R. Agnew, H. D. Noyes, H. Althof, D. B. St. John Roosa; *Albany.*—C. A. Robertson; *Rochester.*—C. E. Rider; *Philadelphia.*—T. G. Morton, E. Dyer; *Baltimore.*—E. Loring; *Chicago.*—J. S. Hildreth, E. Holmes; *St. Louis.*—John Green; *Cincinnati.*—E. Williams; *Detroit.*—J. F. Noyes.

Various committees, on nominations, reception of papers, &c., were then appointed by the President.

Dr. G. A. Hay, of Boston, was appointed the Committee on the Progress of Ophthalmology, for the ensuing year.

On the suggestion of the Secretary, Dr. Rider was elected Reporter, whose duty it should be to report the remarks on papers and cases.

THE PROGRESS OF OPHTHALMOLOGY.

Dr. B. Joy Jeffries then read the report on the Progress of Ophthalmology. The committee deprecated the publication of compilations, handy-books or books of ophthalmology, which become the guide of the practitioner in the particular place where published, and which after all were quasi advertisements. We should rather encourage the publication of Monographs, on topics in ophthalmology. In 1865 one hundred and thirty-seven books were published in our department; in 1866, two hundred and twenty-four. There has been some recognition by Medical schools that ophthalmology should form a part of the curriculum. The necessity of going to Europe for instruction in Eye diseases had turned the attention of the profession and the

laity to the Medical schools abroad and to the necessity for every medical man of a knowledge of French and German. The new operations for cataract were only alluded to since this disease was the subject for discussion. France had now three great text books of ophthalmology, viz. Wecker, Farro, and a translation of MacKenzie. We had none in English. The Ophthalmic Bibliography, from *Zehender's* Journal, was appended to the report, as well as a list of the Eye Hospitals and Infirmaries of the world, compiled from Dr. Knapp's brochure, to which additions had been made by Dr. Jeffries. The report of the committee was accepted with the thanks of the Society, and referred to the Publication Committee.

DELEGATES TO INTERNATIONAL OPHTHALMOLOGICAL CONGRESS.

Dr. F. J. BUMSTEAD, of New York, and Dr. W. W. Seely, of Cincinnati, members of the Society, were appointed delegates to the Congress of Ophthalmologists in Paris.

Dr. J. GREEN then read a paper entitled "Visual Tests, with special reference to the detection of Astigmatism, with an analysis of forty-one cases of Ametropia."

This interesting and valuable paper was an amplification of an article by Dr. Green, in the American Journal of the Medical Sciences for January, 1867.

The Society then took a recess till half-past four o'clock P.M.

AFTERNOON SESSION.

ENUCLEATION OF GLOBE FOR SYMPATHETIC OPHTHALMIA.

The Society came to order, and Dr. J. F. Noyes read a report of a case of "Enucleation of the Globe for Sympathetic Ophthalmia." Osseous degeneratio nwas found in the interior of the eye.

Some remarks were made on the rarity of true bony degeneration, by Dr. Althof; the depositions were generally calcareous, although bony deposition did occur.

Dr. WILLIAMS, of Cincinnati, did not enucleate the globe in sympathetic ophthalmia, but performed abscission, except when bony or malignant growths have occurred or a large foreign body was in the eye.

A rule was adopted restricting remarks on papers to three minutes to each member.

ENCEPHALOID DISEASE OF FUNDUS OF EYE.

Dr. T. G. MORTON read the report of the case of "Encephaliod disease, springing from the fundus of the eye, near the macula lutea, simulating glaucoma."

The patient was forty-one, eye was hard, lens completely cataractous, and there was severe pain. Patient said that blindness had come on suddenly, and iridectomy was done to relieve pain. It did not accomplish the desired result. Two weeks after the eye was enucleated, when pain was relieved. An encephaloid tumor, seemingly arising from the retina, was found two lines from the optic papilla. The pedicle of the tumor seemed to be attached to the choroid; there was no insertion in the sclerotica.

Dr. ALTHOF asked if relief to pain was to be expected from iridectomy in a case of glaucoma, advanced to total blindness, as in this case. Dr. Morton had seen it, and so had Drs. Agnew and Williams (Cin.). Dr. Morton stated in answer to a question, that nucleated and fusiform cells were found on microscopic examination of the tumor. He had accidentally omitted to bring the tumor with him.

TUMORS OF THE BRAIN CAUSING AMAUROSIS.

Dr. E. WILLIAMS then read a paper on "Tumors of the Brain, causing Amblyopia or Amaurosis."

This was a detailed account of several cases of brain disease, in two of which the presence of tumors had been diagnosticated by Dr. Williams, and the post-mortem verified the diagnosis. The other cases were supposed to be of the same nature.

In answer to Dr. Loring, Dr. WILLIAMS remarked that he thought the presence of the tumors might have been diagnosticated without the ophthalmoscope, although mistakes had been made in these very cases, where that aid was not employed. The ophthalmoscopic symptoms were swelling of the optic papilla, turgescence, and tortuosity of the vision, with no change in the arteries, they being straight.

Dr. NOYES made some remarks as to the necessity of thoroughly investigating the condition of the kidneys in neuro-retinitis, in order that we may make an accurate differential diagnosis between the effects on the brain and kidneys. The patient should be watched for a long time, and the *amount of urea* passed be noted.

Drs. W. A. Hall, of Philadelphia, and S. Pollak of St. Louis, whose names were presented by the Committee on new members, were elected members of the Society.

Recess.

SECOND DAY, JUNE 12.

Minutes of previous meetings read and approved.

OFFICERS FOR ENSUING YEAR.

The following named gentlemen were re-elected officers for the ensuing year:—

President.—Dr. EDWARD DELAFIELD, of New York.

Vice-President.—Dr. HENRY N. WILLIAMS, of Boston.

Recording Secretary and Treasurer.—Dr. HENRY D. NOYES, of New York.

Corresponding Secretary.—Dr. H. ALTHOF, of New York.

After some discussion as to a proposed amendment to the By-Laws, making the meetings every other year instead of yearly, the proposed amendment was rejected, and the Society voted, that when they adjourned, it be to meet in Newport, R. I., on the 3d Tuesday in July, 1868.

The following subject was adopted for discussion at the next meeting:—

"The Influence of the Internal Recti Muscles on Binocular Vision."

THE PRODUCTION OF ACUTE GLAUCOMA BY ATROPINE.

Dr. DERBY read a report of "Two cases in which the instillation of Atropine induced acute attacks of Glaucoma." Wharton Jones alludes to this, but Graefe does not. Dr. Derby only adduced the cases in order to provoke inquiry, as he did not at all think that these cases proved the injurious influence of atropine in cases of glaucoma.

Dr. ROOSA spoke of a case of glaucoma, in which Dr. Hinton operated, where the statement of the patient was very decided as to the occurrence of an exacerbation of the disease after the instillation of atropine.

Dr. WILLIAMS, of Cincinnati, never saw any deleterious influences from atropine thus used. He expected these acute attacks, with or without the use of atropine.

PROBES FOR THE LACHRYMAL PASSAGES.

Dr. AGNEW was here called to the chair, while Dr. Williams, of Boston, read a paper on "Modification of Probes for the Lachrymal Passages." Dr. Williams uses probes with bulbous extremities, made of alloyed silver.

Dr. WILLIAMS, of Cincinnati, used a large-sized probe,

when a small one would not enter; also used those made of tin in some cases.

Dr. JEFFRIES stated that Dr. Jeffries, Sr., has been in the habit for years of using probes like Bowman's, bent, having bulbous extremities, and he himself has often turned from the use of Bowman's to these.

Dr. DYER, spoke of further investigation on the subject of "Lenses fractured by hanging," and was allowed permission to present a complete report to the Publication Committee, the investigations and experiments being too recent to allow it to be furnished this time.

DR. JEFFRIES read a paper, entitled a "Ready method of permanently registering the field of vision," with a register for the same." The patient sits down with his head firmly supported, and the field of vision is mapped out in the usual way, cross lines of pack-thread being made over the board, so that the field can be measured.

The Dr. distributed copies of the register among the members.

STRABISMUS.

DR. H. D. NOYES read a paper on Strabismus, detailing some interesting cases. The principal object of the paper was to call attention to the necessity of taking great pains in securing the last of the three effects desired in the operation for Strabismus, viz: 1. The correction of the mechanical defect. 2. Correction of the error of refraction. 3. Securing Binocular vision.

He had lately performed the operation suggested by Liebreich, in which such free incision is made, *i. e.* parts freely dissected up, and afterwards a conjunctival suture inserted, and in a case where there was a convergent squint of seven lines, the final result was a deviation of one and a half lines. There was apparent parallelism for four days. One week after patient could direct both eyes upon the fingers at twelve inches distance. Dr. Noyes showed Javal's instrument for training the eyes to binocular vision, also a stereoscopic frame, contrived by himself, in which all the different kinds of glasses for the correction of Ametropia could be placed.

DR. HILDRETH read a paper on the "Cause of Anæsthesia of the cornea and radiating fibres of the iris, without intra-ocular tension."

DR. E. L. HOLMES read a report of ten cases of Sympathetic Ophthalmia.

DR. H. W. WILLIAMS, of Boston, began the subject of Cataract, by reading a paper on the use of sutures of the cornea after the extraction of cataract.

The Society then took a recess.

SECOND DAY.—AFTERNOON SESSION.

The discussion on cataract was carried on by Drs. Agnew, Noyes, Robertson, E. Williams, H. W. Williams, Morton, and Hildreth. The discussion turned principally on the method of performing the operation and on the after treatment. The flap operation was generally employed, and a bandage afterwards, but no pressure.

DR. NOYES had operated by Graefe's new method in seventeen cases. He advocated a larger incision than recommended by Graefe.

The Society adjourned at 4 P.M., to meet at Newport, R. I., on the third Tuesday of July, 1868.

NOVEL MODE OF SWINDLING A PHYSICIAN.—In a report of the Medical Association of Moselle, we are told of a case in which a woman refused to pay her doctor for more than one visit. She admitted in court that he had cured her of a severe illness; but she said she only sent for him once; if he came oftener, that was his own look-out. The judge took the same view of the case, and the doctor got for his action an order to pay the costs of it!—*British Medical Journal.*

Correspondence.

MEDICAL MATTERS IN PARIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—In Paris, the absence of the excitement afforded by political elections is amply compensated, for a limited circle of people at least, by the continually recurring elections at the Academy, and nominations at the *concours*. You are aware that all the hospitals in Paris are under the control of a central administration, who appoint all the physicians. The appointment is made by the decision of a jury, drawn by lot, from among the actual hospital physicians, who decide the merits of the various candidates for a vacancy, after submitting them to severe clinical examinations. A *concours* of this kind has just terminated, in a manner infinitely disappointing to fifty of the candidates who were rejected, and highly agreeable to the two who were deemed worthy for the important position. The successful candidates were MM. Olliver and Praust.

A new contest is now going on at the Academy, which is busy in deciding upon nominations to the chairs of surgery and medicine, left vacant by the death of Jobert and Rostan. Among the foremost candidates for the first position is M. Langier, who has recently added to his previous claims to distinction by an exceedingly interesting memoir upon cerebral concussion. The phenomena occasioned by this accident are analyzed with the greatest care, and referred to that part of the encephalon which, according to present physiological ideas, presides over the functions compromised. The cerebral hemispheres are certainly affected, for the intelligence, all voluntary and affective faculties, and the consciousness of all sorts of nervous irritation, are entirely suspended. *Unconscious* sensibility, on the contrary, and all movements resulting from reflex action, are, however, preserved, which proves that the pons arolii, and probably the corpora striata and thalami optici are in all their integrity. M. Langier discusses the question, why the hemispheres alone should suffer from a shock that must be transmitted to them through portions of the encephalon that remain uninjured. He accounts for this immunity on the part of the pons, the bulb, etc., by the fact of their superior firmness of structure, and the more secure position of their gray masses, which, being in the centre of the white tissue, are much less exposed to shock than the gray substance of the hemispheres distributed over their surface.

It is not certain whether this memoir will elect M. Langier, but it is discussed in his favor. Another illustration of the value of disease in dissecting apart the involved functions of the brain, is furnished us this week by a most interesting case at the Hôpital St. Antoine, in the service of M. Jaccaud. It was a case of aphasia, the disease that has been rendered so famous by M. Broca's theory, which attaches it to a lesion of the third anterior convolution of the *left* cerebral hemisphere. The accident is not uncommon, but the opportunity for verifying the diagnosis by an autopsy is comparatively rare, as the disease is rarely or never directly fatal. Hence this case, which afforded such an opportunity, is one specially valuable.

The patient in question was already a victim to Bright's disease of the kidney, for which he had been in the hospital since last June. At the period of the accident he suffered from an extensive œdema, without ascites; albumen was abundant in the urine; he presented, moreover, a systolic souffle at the point of the

heart. On the 22d of January, without any premonitory symptoms, this patient suddenly discovered that he had lost the power of speech, and on the morning visit, the next day, he was found in a state of great disquiet, pointing to his lips and tongue, indicating by signs that he wished to speak but could not. There was not the slightest lesion of any of the limbs, and at the face only a slight paralysis of the zygomatic and elevator muscles of the right side of the mouth, which was drawn a little to the left.

The understanding was not in the least impaired; he took up any article that was named to him, but could not name them himself. When a person pronounced before him a word distinctly articulated, he examined carefully the motion of the lips, and succeeded in uttering some monosyllable, as "bien," "vous," but that was all. He was equally unable to write as to speak, never getting beyond the first letters of his name.

In presence of these symptoms, and on account of the mitral insufficiency, M. Jaccaud pronounced a diagnosis of lesion of the third frontal convolution, probably at the left (since that is the case seven times out of ten), and probably in consequence of an embolus.

The aphasia began to disappear by the end of the 30th, and by the end of February was entirely gone. The patient died on the 22d of April, and at the autopsy the diagnosis was fully confirmed by the discovery of—first, complete fatty degeneration of the kidneys; second, vegetations on the mitral valve, and insufficiency; third, buried in the white substance of the third frontal convolution of the left hemisphere were two hæmorrhagic cysts, which contained some drops of liquid. One of these cysts was the size of a pea, and situated at the right of second, whose volume was three times as considerable. The surface of the section was distinct and well limited; not only the lesion did not extend beyond the convolution in question, but the gray matter of that was untouched, and from the exterior appeared perfectly healthy. The other parts of the encephalon, as also the membranes and the arteries, were examined with great care, and found perfectly sound.

Hence this case brings fresh support to the theory that places the power, not merely of speech, but also expression by writing, in this limited part of the brain.

Among the candidates for the vacant place in medicine at the Academy, M. Hérard is one of the most prominent. His claims to the honor chiefly rest upon a work that he has published this year upon pulmonary consumption. The initial idea of this striking book was originally promulgated in Germany by Reinhardt, but M. Hérard and his colleague, Cornil, have done much, not merely to popularize Reinhardt's views, but to bring to their support abundant clinical demonstration. You are aware that Reinhardt completely upsets the old descriptions given by Laennec and Louis of the cheesy tubercle. According to recent microscopical researches, the yellow masses thus denominated are formed, not by the ulterior development of a heterologous deposit, but of a pneumonia, excited by the presence of the crude tubercles in the connective tissue of the lung. This pneumonia differs from ordinary acute pneumonia, rather in its anatomic and microscopic characters, than in its constitutional effects. Instead of an exudation of fibrine into the alveoles, there is an exudation of pavement epithelium and leucocythes. In other words, it is a *catarrhal* pneumonia, similar with that caused by artificial experiment. To this pneumonia Hérard and Cornil refer all the general symptoms of phthisis, the fever, emaciation, and destruction of the vital forces. They maintain that the presence of the crude tubercle in the lung excites *no* general disorder, and it may remain latent for an indefinite period, until, generally in consequence of some special accident, the tissue surrounding it inflames. This inflammation may subside spontaneously or under the influence of treatment, but relighted again and again, it finishes by entering upon the cheesy stage (*pneumone caseuse*). At this stage the contents of the alveoles liquify, the hepatised lung softens, and the cavern is formed which for so long has been exclusively attributed to the softening of the tubercles. These also soften, but their size always remains the same as that of the original gray granulation. Even when softened they may be distinguished from the masses of pneumonic lung through which they are disseminated, by the presence of small nuclei and the cellules, called by Robin cytoplastians.

In consequence of this view of the anatomy of phthisis (which approaches in its nature somewhat to that proclaimed by Broussais), M. Hérard lays special stress upon local revulsives in the treatment, iodic frictions, blisters, and the actual cautery. The tonic and stimulant general treatment is of course also maintained, though our American use of alcohol is rejected. To a certain extent, a moderate use of tartar emetic, as recommended by Foussagrines, is counselled.

This treatment does not procure brilliant results in the hospitals, where the patients generally are too far advanced to be saved, but M. Hérard declares that a fair share of success may be obtained in private practice, where the disease is treated at the very beginning.

M. Marriothe communicates to the *Bulletin de Thérapeutique*, an account of some clinical experiments made by himself this winter with muriate of ammonia, in the treatment of catarrhal fevers that have been epidemic in Paris. These fevers assumed a remittent or intermittent type, without losing their distinctively catarrhal character, but proved quite obstinate to sulphate of quinine. In accordance with a suggestion by Schmidtmann, who was in the habit of giving muriate of ammonia in the declining period of gastric fevers when they assumed a periodical form. M. Marriothe tried the experiment, at first in some cases complicated with very severe neuralgies, which interrupted sleep, and even extorted cries from the patient. The effect of the muriate was surprising. In mild cases the febrile attacks and the neuralgies ceased upon the first or second day; in more severe forms the success was not complete till the third or fourth, but there was always amelioration by the first or second.

M. Marriothe thinks that the salt has an important influence in moderating the erethism of the mucous membranes, but that, besides, it acts directly on the nervous system, without the occurrence of any intermediate phenomena, as vomiting, sweating, diarrhœa, etc. The dose found necessary to arrest the febrile attacks and calm the neuralgia, varied from thirty to sixty grains in the course of the day, being administered in portions of 7–15 ʒ every three or four hours.

An operation that Dr. Brown has done much to bring into favorable notice in England, is beginning again to excite the attention of French physicians. I mean the capital operation of ovariotomy, upon which M. Boinet has just read an elaborate report before the Academy. The report begins with reference to an American, the first who practised ovariotomy with the definite intention of extirpating the diseased organs, Dr. Ephraim MacDowell, of Kentucky. This surgeon, between 1809 and 1830, operated thirteen times, and obtained eight cures. Baker Brown reports twenty-nine successful cases out of thirty-two operations. Even were the success in much smaller proportion than this (and the recent exposé of Brown's character renders us cautious about accepting his statistics), the oper-

ation would be legitimate in a disease that conducts its victims almost inevitably to the grave, the deaths being 95 in 100. M. Boinet reprobates the timidity of the French surgeons, who have so long recoiled before this operation, and proceeds to give many useful hints upon the precautions necessary to insure success.

In the first place, the operation should never be performed at a hospital, where peritonitis invariably follows the opening of the abdomen; a healthy, isolated locality should be selected, and a room prepared whose temperature should be maintained at 20 to 25 degrees centigrade. Secondly, the nature of the cyst must be carefully considered. If it be simple, unilocular, containing a liquid, clear, limpid, and serous, or even purulent or sanguinolent, the operation is inappropriate. Nelaton's system of iodine injections should be first tried. But if the liquid, though at first serous, becomes unctuous and fatty, ovariotomy is the only resource. Other proofs that the cyst is multilocular, or that it contains pathological productions contra-indicating the use of iodine, signs of the increase of the tumor, and exhaustion of the patient, are circumstances that should also call for the operation. Among the contra-indications should be reckoned the existence of grave complications, an early stage of the disease, pregnancy, or tumors in the uterine walls.

The operator should place himself at the right or left side of the patient, instead of between the knees, as recommended by some surgeons. The incision should be made on the median line, and of sufficient size to admit the free introduction of the hand in the cavity, for the purpose of recognising the size and position of the tumor and the extent of the adhesions, which exist three times out of four. When these adhesions are slight and can be easily torn, they occasion no inconvenience; but if large and resistant, their action frequently causes dangerous hæmorrhage. The dangers of too short an incision have been frequently exposed; the adhesions are not distinctly perceived, the cyst is imperfectly grasped, the other ovary cannot be seen, the pedicle is tied with difficulty, and sanguineous effusions may take place in the abdominal cavity without the knowledge of the surgeon. Should the first incision prove too short to avoid these inconveniences, a second can always be practised with safety.

The incisions should divide the different layers of the abdominal wall in succession, to avoid too sudden entrance into the cyst. As soon as this is discovered, the hand should be introduced, to ascertain the existence of adhesions or neighboring tumors. In the second case, it is only necessary to enlarge the incision; in the first, the adhesions must be detached by the hand, or destroyed by the scissors or hot iron. They should not be torn.

Before tapping the cyst two assistants should press upon the abdominal walls, in order to force the cyst to project between the lips of the incision. The puncture is then made with a trocar, and by means of the foregoing precaution the liquid is prevented from running into the peritoneal cavity. If there is more than one pouch, the first should be held by pincers, or tied, while the others are drawn out of the cavity. If the cyst, on its retreat, draws a portion of its adherent intestine, it is important that this be detached; if that be impossible, a piece of the cyst must be cut out, and left attached to the intestine. Care must be taken, however, to remove the internal secreting membrane from this fragment.

All bleeding vessels, whose volume is not too considerable, should be twisted, or cauterized with a hot iron or the perchloride. Only when this method is impossible should the vessels be tied.

The wound should not be closed until the last drop of liquid has ceased to flow. An eminently useful precaution consists in placing in the inferior angle of the wound, or in the recto-vaginal cul-de-sac, a caoutchouc tube, by which any liquid subsequently effused may drain off. MM. Keith and Koeherle attribute a great number of their successes to the observance of this precaution. Boinet has no dread of the introduction of air into the peritoneum, attributing all inflammation to the action of liquids, and not air.

A double line of sutures is necessary, one deep, the other superficial. M. Boinet decides in favor of including the peritoneum in the suture, to avoid the danger of this membrane contracting adhesions with the intestine. The pedicle should be compressed by a toothed clamp, which has the advantage of compressing the tissues and preventing hæmorrhages. If the pedicle is voluminous, it should, however, be tied, or the ligature combined with the clamp. When the size of the pedicle, or its insertion on the uterus, presents unusual difficulties, a thread of ligature should be passed around it before the cyst is cut away.

M. Boinet concludes, "that the ovariotomy should be accepted with as much enthusiasm as all other capital operations; and that now that the bases of diagnosis are better assured, and the operative procedures more perfect, the subsequent treatment better understood, more advantageous results will doubtless be obtained."

M. Demarquay, surgeon of a Maison de Santé, presents a report on the topical application of iodoform in the treatment of cancer of the uterus. This agent employed in the crystalline form, in a dose of 7 to 15 grains, is mixed with a sufficient quantity of butter of cocoa, and the suppository thus formed, introduced into the vagina, or an ulceration of the carcinoma, if that exists, —a tampon of cotton is placed in front. The general effects are slightly observable, although the iodine from the drug (C^2HI^3) is absorbed and may be discovered in the saliva and urine. But the local suffering is almost infallibly soothed; the swelling of the abdomen diminishes; and the ease procured lasts as long as the medicament is continued, is broken up by the interruption of its administration, and reëstablished when that is renewed.

Dr. Morel, the distinguished alienist, writes an interesting article in the Archives of Medicine for May, upon progression in hereditary insanity and nervous diseases. Not content with the vulgar fact of hereditary influence in the transmission of such disorders, he, in company with an army of modern *confrères*, seeks the laws that govern this hereditary transmission. I have not space left to enter into all the details of his curious paper, I can only mention three or four of the most striking conclusions, drawn from a great number of facts: 1st. Insanity, epilepsy, hysteria, chorea, eccentricities, dypsomania, etc., are only the branches of an identical constitutional vice of the nervous system, and may be transformed, the one into the other, by way of hereditary transmission. 2d. Such transformation is more frequent than the transmission of the same form of disorder. When a simple eccentricity of a parent becomes insanity in a child, &c., the hereditary taint is said to be progressive ascendant, and the opposite case progressive descendant. 3d. Whenever the several children of parents presenting a nervous taint, are *markedly dissimilar* in appearance and character, the taint will almost surely be transmitted, and progressive ascendant. It seems in this case as if the whole force of family likeness was concentrated in the depths of the nervous system. 4th. In such families it is common to observe that one or more of the members are gifted with remarkable intellectual ability, while others are idiots.

The third proposition especially constitutes the theme

of M. Morel's present paper. The fourth identifies his views with those of Dr. Moreau, who, in his remarkable work on morbid psychology, unhesitatingly ranks genius among the neuroses, and assigns to it an origin identical with that of epilepsy, insanity, and idiocy.

CONGESTIVE FEVER IN THE SOUTH.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—In the reported proceedings of the Medical Society of the County of New York, April 1, 1867, it is stated that "the history of congestive fever was next discussed, especially as it appeared in the Valley of the Mississippi and on the borders of the Gulf of Mexico, where it was so prevalent and fatal. The conclusion was reached that prior to the year 1834, true congestive fever was unknown there. Not that it was unusual to find congestion complicating fevers and increasing their danger; but that the congestion which gave distinctive character to the fever, which first startled the people of that region in 1834, culminating in 1843, was attended with phenomena so exceptional as to demand a new name."

The impression which this statement is calculated to make upon the professional mind is, I think, erroneous. It certainly is a mistake to say that congestive fever in all its intensity and fatality was unknown in that quarter until 1834. When I went to that country in 1819 this form of fever was common, and it had been, as represented to me at that time, for many years before—even from the first settlement of the country. In some parts of Louisiana, and the southern portions of Alabama and Mississippi, congestion was such a distinctive characteristic of the prevailing fevers, that they were commonly designated by the term *Cold Plague*, and the mortality from this form of disease was greater before 1820, and even before 1830, than it has been since. But the same congestive characteristics have accompanied the graver forms of fever to the present time, and with as little variation of symptoms as has attended upon small-pox during the same period in New York city, or elsewhere. In some years it is more violent and fatal than in others, but people die of it every year from Memphis to the Gulf. As stated in my published lectures on the subject, "my belief is, the character of the disease has undergone little change since the time of Hippocrates. Names alone have changed;" and in the South we have been treated with many of these changes, not by any means beginning at so late a period as 1834.

As congestive fever is the great outlet of human life in the South, and the form of disease eminently to be feared by immigrants, it may be of importance, whatever may be said of its pathology and therapeutics, that its "*history*" be correctly written.

Truly yours,

A. P. MERRILL, M.D.

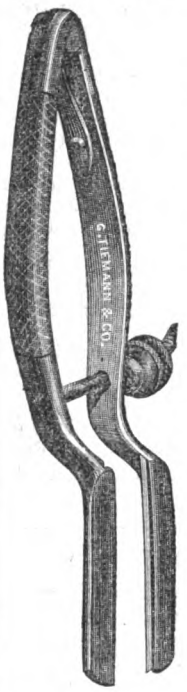
New York, June 20, 1867.

POISONOUS BREAD.—M. Nickles, Professor of Chemistry at Nancy, has just discovered a circumstance which may turn out to be of great importance to public health. It seems that bakers have been lately in the habit of heating their ovens with old painted wood got cheap from the demolition of houses. But bread baked in such an oven acquires poisonous qualities from the white lead, verdigris, and other noxious substances contained in the paint; and M. Nickles shows that these substances are absorbed by the crust, and do not penetrate to the crumb.

New Instruments.

THE MODIFICATION OF SMITH'S PILE CLAMP.

THE accompanying wood-cut represents a very useful modification of the Clamp of Mr. Henry Smith, of London. The original was arranged so that the blades closed like those of a scissors, and when the hæmorrhoid was grasped it necessarily became more or less pinched at one point, while it was comparatively free at the other. This objection to its use, when the sufferer was not under the influence of chloroform, was a serious one, causing much unnecessary pain, and even when the patient was insensible to pain the pile was not uniformly compressed. Mr. Stohlmann, of the firm of Tiemann & Co., of this city, appreciating the difficulties in the way, contrived a modification, by which, as will be seen, the two blades come together perfectly parallel to each other, and by means of the screw in the handle, are made to close evenly upon the mass to be separated. The hæmorrhoidal mass, being tightly inclosed, may be simply strangulated, and afterwards separated with the knife, and a hot iron applied to the surface; or this latter may be done, if the tissue is not too dense, without the knife. If the knife alone is used hæmorrhage may be prevented by applying persulphate of iron in powder or solution, to the severed part before the clamp is removed. The surfaces of the blades which are applied to the integument of the patient, are guarded with ivory plates, in order that no heat be communicated to the sensitive parts when the hot iron is used.



Obituary.

BENJAMIN OGDEN, M.D., who was long and favorably known as one of the earliest psychologists of this country, expired at College Point, L. I., on Tuesday, June 18, aged 70 years. He had for some months been a sufferer from paralysis, but a mitigation of his symptoms at one time seemed to indicate an ultimate recovery, and as it was, his death occurred somewhat suddenly. At the last session of New York Academy, after several eulogies upon the deceased, the following resolutions were unanimously adopted:

Resolved—That the Academy hears to-night with heartfelt sorrow of the death of one of its original founders, Doctor Benjamin Ogden, who died yesterday, June 18.

Resolved—That in Doctor Ogden we recognize one who has adorned and beautified his profession by nearly half a century of usefulness in this the city of his birth; nor was the knowledge of his worth confined to its narrow limits, for the brightness and goodness of his character, and his reputation and his speciality as an alienist, were co-extensive with our country.

Resolved—That he who was so foremost in every good word and work deserves our warmest esteem, and should excite and stimulate our earnest emulation.

Resolved—That the Academy will attend the funeral of Doctor Ogden, which will take place from St. James Lutheran Church, in 15th Street, between 3d and 2d Avenues, on Thursday (to-morrow), at 2 P.M.

S. Pomeroy White, M.D., died June 6th, 1867, of typhus fever, in the 66th year of his age. The New York Academy of Medicine, in memory of the deceased, passed the following:

Resolved—That the New York Academy of Medicine learned with profound regret of the death of one of its first, its oldest, and most esteemed fellows, Doctor S. Pomeroy White, who died on the 6th day of June instant, of typhus fever.

Resolved—That the Academy bears testimony to the lustre which in early life Doctor White shed upon American surgery; as well as to a long life in our midst of useful and honorable professional career.

Resolved—That the profession has lost a valued and useful member, the community an honorable and upright man, his family a fond and devoted head; and we desire to express our sympathies in this their bereavement.

Resolved—That a copy of these resolutions, signed by the President and Secretary, be furnished to the family of the deceased.

Died on Sunday evening, June 16, at the house of Dr. E. R. Squibb, in Brooklyn, Robert O. Abbott, Brevet-Colonel and Surgeon, United States Army, aged 43 years.

The New Hospital on Ward's Island—Adopting the suggestion of Mr. Richard O'Gorman, the Commissioners of Emigration have resolved to give the new Hospital on Ward's Island the name of their President, Mr. Gulian C. Verplanck.

The State Medical Society of Iowa held its last meeting May 22, 1867, at Davenport. The attendance was large, and many interesting papers were read by different members. The following officers were elected for the ensuing year: President—Dr. William Watson, of Dubuque. Vice-President—Dr. Edward Whinery, of Fort Madison. Recording Secretary—Dr. A. G. Field, of Des Moines. Treasurer—Dr. M. B. Cochran, of Davenport. Corresponding Secretary—Dr. E. J. B. Statler, of Marshalltown.

Homœopathy on the Eye.—The Directors of the New York Ophthalmic Hospital, having substituted homœopathy for the allopathic system of cure, have employed Drs. Allen, Bacon, Wetmore, and Leopold. The retiring physicians are Drs. William F. Holcombe, Giovanni Ceccarini, J. M. Carnochan, and Marcus P. Stephenson.

Condition of Poor-Houses of New Jersey.—In the report of the State Sanitary Commission to the Governor of New Jersey, for the year 1866, we find the following allusion to the condition of the poor-houses:

"In connection with our attempted investigations as to the insane and idiotic in county and township poor-houses, we instituted some inquiries in reference to these institutions, and it has become quite apparent to us that in parts of our State 'the poor system' is essentially defective; while in some parts the poor are farmed out to the lowest bidder, in others they are congregated together without sufficient regard to the use of those means which prevent pauperism as well as provide for it. On the other hand, we are not without models in our own State, which other towns and townships might imitate, and our error is in having no public officer whose duty it is to regard these and other interests of public hygiene and to bring them to the attention of those who are themselves conscious of defects, but for the want of such correspondence and information know not how best to remedy existing evils. It is noble to provide for the afflicted and the destitute, and right to punish the criminal, but the philanthropist who sees one generation of paupers providing the next, who beholds insanity too often transmitted or originated as a result of errors in marriage or habits, and who sees vice spring out of the filth and bad air and unfit homes, and then subjected to punishment, not reformatory, cannot but inquire if it would not be wiser and more economical legislation, by sanitary regulation and information, to dry up the sources of degradation as well as to make provision therefor. Ounces of such prevention are better than manifold pounds of cure."

Qualifications for a Surgeon.—Every aspirant for surgical honors is sure to be told early in his course by some kind friend or other, that to be a good surgeon a man must have a lion's heart and a lady's hand. Well—he looks down at a hand of anything but feminine proportion, and looks back to his sensations at the first operation he witnessed; and he is apt to conclude that he has chosen the wrong path in life. By-and-by he finds that by constant practice in the use of instruments his fingers have acquired a new delicacy and flexibility; and he finds, too, that as the source of the lion's courage lies in consciousness of strength, so the moral courage and firmness typified by the lion's heart, may come to him as sure results of better knowledge and training and self-reliance. Uncertainty and ignorance can hardly produce anything but cowardice or rashness; true courage is associated with judgment and reflection. —*Introductory Address at St. Thomas's Hospital*, Oct. 2, 1865, by William M. Ord, M.B., London.—*Medical Times and Gazette.*

Yellow Fever.—In consequence of the arrival, on the 24th ultimo, of a ship at Fortress Monroe from Matanzas with yellow fever on board, the Health Officer of this Port has orderdd all vessels arriving from the infected port to anchor at the Lower Bay. The disease is also reported to have made its appearance at New Orleans.

CLINICAL THERMOMETRY IN DIPHTHERIA.*

By JOSEPH G. RICHARDSON, M.D.,

DELEGATE FROM THE CAYUGA CO. MEDICAL SOCIETY, NEW YORK.

Though simplest among the many contributions which during the past decade medicine has received at the hands of her sister sciences, such as the endoscope, sphygmograph, and laryngoscope, the clinical thermometer seems to promise the most general and practical advantage, inasmuch as it requires for its application no prolonged experience or particular instruction, and may be usefully employed in almost every case which demands the study of either specialist or general practitioner. Its instrumental aid has thus far been invoked and its capacities tested more or less completely in a majority of the diseases which come beneath our notice; but among the minority which have hitherto remained almost untried by its standard, probably none are of more importance than diphtheria, which, on account of its general prevalence and its obscure etiology, as well as its fatality, so great and sometimes so unexpected, appears to require further elucidation at the hands of every scientific physician. The seeming neglect in this respect which it has undergone may be, no doubt, in part ascribed to the fact that it is a disease not very common in our chief cities, and especially unusual in those large hospitals where, judging by notices published in medical periodicals both of this country and of Europe, most thermometric researches thus far recorded have been carried on.

The circumstance of being located in an intensely diphtheritic region, by rendering necessary an almost daily intercourse with different grades of the affection during the past winter, has afforded me an opportunity to supply this omission and to record numerous observations upon the range of temperature in diphtheria, of which I propose to give an abstract in this paper, and also to set forth a few important deductions as to their prognostic and therapeutic worth, which I hope may at least furnish a basis of data for more extended investigation, and constitute a nucleus around which may be gathered other facts which shall combine with these to afford invaluable assistance in many a future struggle with this formidable affection. Who, indeed, that has been called upon to combat this most deceitful malady, and has beheld the insidious foe creeping onward and downward towards the tracheal aperture with an unseen and stealthy progress, which, if unchecked, must soon hurry its victim to the grave, has not ardently desired some feasible method of discovering how rapid was its course when it passed beyond the bound of direct vision, and how soon the cessation of its advance might be expected? that he might on the one hand inspire with new hope the despairing patient, or on the other arouse to new energy his own and the attendants' efforts. Or, again, which of us who has been called upon to undertake the heavy responsibility of performing or abstaining from tracheotomy has not felt, as the diphtheritic patient, gasping for breath, turned upon us his imploring eye with a whispered but eloquent appeal for relief from his agonizing sufferings, an anxious longing for some test which should indicate with an approach to certainty how near the violence of the disease was spent, and also what stock of failing strength remained to support the system under the operation? Such a means we have offered to us in the clinical thermometer, which for its aid to our profession, not only in diphtheria, but likewise in others of "the ills that flesh is heir to," must, I think, hold its place with the stethoscope of Laennec and the plexiimeter of Piorry.

Perhaps these statements can be most satisfactorily illustrated by transcribing from my note-book the records of two or three severe cases, and then giving an abstract of results from the whole series of thermometric observations, which are about sixty-five in number. The first case selected was remarkable for the high temperature (being more elevated than any other noted), the quantity and rapid formation of the exudation thrown out, and the promptness with which it yielded to treatment. Miss Sarah S., aged seventeen, of fair complexion, nervous temperament, and rather delicate constitution, was attacked on the 21st of February, 1867, with very severe headache, pains in the back and limbs, accompanied at first by slight rigors, which gave way after a few hours to high febrile action. About 9 P.M., when I saw her first, her pulse was 132 per minute, and her temperature, as ascertained by introducing the bulb of a clinical thermometer into the axilla, closing the arm tightly over it, and allowing it to remain eight minutes, was found to be 102¼ degrees. Her right tonsil was much swollen, deeply injected, and very painful, but had only three small spots near its centre; her strength was much prostrated, so that she sat up with difficulty for me to examine her throat. On the following morning, February 22, her pulse was 120 per minute, her temperature 102 degrees, the right tonsil was covered with a patch of thick, heavy, false membrane, whose area was estimated at 70 square lines, while the left exhibited a similar deposit over about half that much surface. Her headache was much relieved, although the pain in her limbs and prostration of strength remained about the same; her tongue was much coated, breath very offensive, and anorexia complete. In the evening her pulse had fallen to 100 beats per minute, and her temperature to 100 degrees; the superficial area of false membrane on each tonsil was about the same as observed on the previous visit, but the circumjacent redness had somewhat lessened; she had hardly any headache; the pains in her extremities were much diminished; her appetite had commenced to return, and she had attempted to sit up during the afternoon, though compelled soon to relinquish the effort on account of the nausea which it produced. February 23.—I found that my patient had slept well the night before, and that her relish for food was greater, although the tongue was much furred, and she had still a little headache; her pulse beat 88 times in the minute, and her temperature had sunk to 99¼ degrees. Most of the false membrane had disappeared; on the right tonsil a surface of about 20 square lines, and on the left one of 30 square lines was, however, still covered; the soreness at the time of my visit greater on the left side than on the right, although the latter had been first attacked. February 24.—Patient sitting up; pulse, 108; temperature, 98¼; right tonsil clear of false membrane; patch on left tonsil of about 5 square lines, situated near the top; has a little pain on swallowing, but less than yesterday; headache and pain in the limbs entirely gone, appetite good, tongue cleaner, fauces almost natural in color. February 25.—Pulse, 84; temperature, 97½; throat quite clear of deposit, although the act of swallowing is still accompanied by a little pain; no headache; feels stronger; and has a good appetite, with whose assistance she rapidly convalesced.

Case II. is chiefly worthy of note as showing the energetic efforts made by nature to overcome a violent

* This paper was read before its appropriate section at the late meeting of the American Medical Association, at Cincinnati; but on account of the limited number of cases observed, returned for confirmation of its conclusions by further data. In order to obtain these the author invites the assistance of any members of the profession who may feel interested in the subject, assuring them that their contributions will be most thankfully acknowledged.

attack of the disease, aided by unfavorable hygienic influences. It is that of Mr. Gilbert C., aged twenty, of vigorous frame and strong constitution, having never been sick before in his life, who was attacked on the 1st of March, 1867, with severe sore throat, headache, pains in his limbs, &c.; but, being unacquainted with illness, refused to see a physician until the morning of the 4th of March, when I was sent for and found him suffering from a good deal of headache and pain in his throat, which upon examination exhibited great swelling of the tonsils, so that they met in the middle, pushing the elongated uvula forwards; the right tonsil was the most affected, being covered with a layer of yellowish false membrane, estimated at 170 square lines in area, while the left was coated to the extent of about 80 square lines; his pulse was 80 per minute; temperature, 99½. At 6 P.M. of the same day his pulse beat 90 per minute, and his temperature had risen to 101½ degrees. He stated that he thought he had taken more cold the evening before, that his throat was fuller, and he felt more as if he must strangle during the night. March 5, at 10 A.M. his pulse was 87; his temperature, 100¾; had great difficulty of breathing all night—so much so that he was unable to lie down, but sat up in a chair; was too distressed to admit of any examination of the fauces. At 8 P.M. on the same day his pulse was 84, and his temperature 100 degrees. March 6, 9 A.M.—Pulse 86, and more feeble; temperature, 100 degrees; throat feels sore, but not much painful when at rest; on examination found to be less red and tumefied, so that the tonsils lay one quarter of an inch apart. The false membrane on the right tonsil covered about 60 square lines, on the left 30 square lines. Sat up all night in his chair, but dozed a little; ate a good breakfast with some relish; but his whispering voice and slight croupy cough made me feel very anxious in regard to his safety. At 6 P.M. his pulse was 96; his temperature, 99½. He complained, however, that his head ached a good deal, and both he and his relatives dreaded the occurrence of brain fever, to which they stated their family was predisposed. The visit this evening was made in consultation with Dr. Test; and although the suppressed croupy cough (much more marked since morning), the severe headache, and the intense feeling of strangulation, all combined to render our prognosis unfavorable, yet the regular decrease of temperature, as indicated by the thermometer, from 101½ on the evening of the 4th to 100¾ on the morning, 100½ on the evening of the 5th, 100 in the morning, and 99⅔ at the time of our visit on the 6th, encouraged us to entertain the hope that the disease was so far abating, that should these symptoms be, as we anticipated, the results of partial separation of the false membrane, about to come away, a favorable termination might yet be expected.

On the morning of the 7th, at 9 A.M., I found his pulse only 76; his temperature, 99½; his cough loose and resonant, and his breathing comparatively unembarrassed. I learned from his attendants that although the cough continued to become more croupy during the night, about 5 A.M. something seemed to loosen in his throat, feeling, as described in the patient's own words, as if "a cork was going backwards and forwards in his windpipe," which flapped up and down with a noise audible to his nurse for about half an hour, and was finally expelled with a violent struggle, during which suffocation appeared immiuent. Since that time he had felt much easier, slept for about an hour, and was able to breathe and swallow with much more comfort.

At 6 P.M. on the 7th I found his condition still improved, except that his pulse, which was 84 per minute, was rather more compressible; his temperature was 99⅔.

I learned that about four and five o'clock that afternoon, respectively, he had severe choking spells, and after violent efforts coughed up two pieces of false membrane, which had been saved and were shown to me. The larger fragment was about two and a half inches long, half to three-quarters of an inch broad, and one-sixteenth of an inch in thickness. The smaller was nearly an inch square, assumed when floated out in water a semi-cylindrical form, and bore upon its thin convex surface distinct impressions of three of the tracheal rings, rendered more distinct by the fact that the intermediate portions of membrane were stained of a pinkish tint, apparently from the extravasation of blood.

March 8, 9 A.M.—His pulse beat 88, his temperature stood at 99¾ degrees. The tonsils were less swollen, and the exudation so far diminished that it covered an area of only about ten and five square lines on the right and left sides respectively. Had a severe attack of epistaxis last evening, notwithstanding which he slept some four hours, and felt better at the time of my visit.

In order to avoid occupying valuable time unnecessarily, I will proceed no further with particular notes of this case, merely stating that after a relapse of diphtheria, apparently the result of taking cold, he gradually improved until the 10th of April, when I was recalled to his bedside, and found him the subject of double pneumonitis, contracted by sitting at a window without a vest on, which proved fatal on the fifth day of its course.

Case III.—Miss Caroline S., æt. thirty-six, medium height, dark complexion, naturally of good constitution—perhaps a little debilitated by an attack of diphtheria about two years ago—was seized with sore throat on the 27th of April, 1867, while riding out after dark. When called to see her the day following, at 5 P.M., I found her pulse 120, her temperature in the axilla 102 degrees. The right tonsil was a little swollen, and had two or three small specks of exudation upon it; the left was a good deal tumefied and reddened, showing near its upper part a patch of whitish false membrane, covering an area of 30 square lines. April 29, at 5½ P.M., I found her pulse 112, her tempetature 101 degrees. Her headache was much less, but her throat was more sore and the difficulty of swallowing greater; slept about half of last night, and has eaten some food, but without relish. False membrane on right tonsil about 10 square lines, on left tonsil 140 square lines; palate very œdematous, but not coated with exudation. April 30.—Her pulse was beating 108 times per minute; her temperature, 101½ degrees; respirations, 24 per minute. Left tonsil less sore and less swollen, but entirely covered with a patch of false membrane, estimated at 180 square lines. Right tonsil felt sore to-day for the first time, and at the period of my visit was quite painful and swollen, coated with about 100 square lines of exudation. Slept a little last night, but was awake often. Feels weaker than yesterday, so that it makes her dizzy to try to stand erect; but the headache and the pain in her limbs rather easier.

May 1.—Her pulse beat 104, her temperature 100½ degrees, and her respirations 26. Left tonsil exhibited 120 square lines of false membrane, which was quite ragged and much loosened at the upper part; right tonsil more coated than yesterday, showing about 140 square lines. Had no pain in her limbs, and less in her throat, but feels much weaker, and her head aches more.

May 2, 5 P.M.—Pulse 104, temperature 100½ degrees. Slept better the night before, and had neither headache nor nausea during the day; did not feel any weaker than the day previous. Right tonsil about the same coating as yesterday, 140 square lines; left tonsil 70 square lines, and reduced to about half the magnitude it had yesterday.

May 3.—Pulse 100 per minute, temperature 100 degrees. Left tonsil clear of exudation, but the posterior half arch behind it is covered with an elongated patch of

about 30 square lines in area; false membrane upon the right tonsil estimated at 90 square lines. Palate still œdematous, but less so than yesterday. Soreness of throat diminished. No headache, no nausea. Slept most of the night, but perspired freely since daylight, and felt weaker than the day previous.

May 4.—Pulse 92, temperature 99¼ degrees. Left tonsil quite clear, and its posterior half arch only coated to the extent of about 5 square lines. Exudation on right tonsil estimated at 70 square lines. Slept all night; throat less painful; and although she took less stimulus, she felt stronger than she did the day previous at the time of my visit. Being the last time I saw the patient before my departure for Cincinnati, I can give no further notes of the case, which I hope, however, has by this time progressed to a favorable convalescence.

As these three well marked examples of the disease give a very fair exposition of the thermometric changes which occur during its course, I need occupy no more time in the narration of particular cases, but may proceed at once to detail briefly an abstract of all the observations I have made in the whole series of twelve attacks. Of the *first day* of any attack I have no record. On the second my notes give the mean temperature 100½, an average of thirteen observations, of which the highest was 102½ degrees, occurring in two instances, and the lowest 99 degrees; the average pulse on the same day was 104 beats per minute. On the third day I find the mean temperature, as deduced from fourteen observations, 99⅔ degrees; the pulse averaging 96 beats per minute. On the fourth day the average of ten observations gave a temperature of 98⅘ degrees, while the average pulse had fallen to 85 per minute; while on the fifth day the average temperature had reached the normal standard of 98½, while the pulse beat 72. I should mention that two of these patients were the subjects of valvular disease of the heart, and that the slow rate of their natural pulse has some slight effect in reducing the average frequency of the pulse as above given.

While the cases thus detailed are perhaps too few in number to insure absolute certainty for the following deductions, which further observations may in some minor respects modify, yet it would seem that we may safely draw the following general conclusions:

First—That the thermometric range in diphtheria is less elevated than that of most other acute diseases, and that hence in marked cases a comparatively low temperature of 102 or 102½ degrees should not mislead the physician into considering the attack as of little importance.

Second—That as the changes of temperature appear to bear a closer relation to the amount of false membrane than do the variations in the pulse, we may on the one hand feel more assured of approaching convalescence by its fall, or on the other hand must entertain graver fears for our patient's safety, should it steadily rise, than by finding corresponding alterations in the rapidity of the heart's action.

And *thirdly*, therefore, that in these alarming cases where the disease invades the larynx, and we are called upon to perform tracheotomy, if it affords any hope for the patient, a careful record of the thermometric changes supplies us with the best guide hitherto discovered, whether the exudation will be apt to extend rapidly further, and so render that serious operation utterly fruitless.

THE CINCINNATI JOURNAL OF MEDICINE has been transferred to Indianapolis, and its name has been changed to that of *The Western Journal of Medicine*. Dr. T. Parvin is the editor.

REMARKS ON THE

EMPLOYMENT OF CHLOROFORM

AS A THERAPEUTIC AGENT, WHEN TAKEN INTO THE STOMACH.

By E. McCLELLAN, M.D.,

ASSISTANT SURGEON AND BREVET MAJOR, U.S.A.

THE internal administration of chloroform, in the treatment of delirium tremens, and other neuroses, which has lately been revived with much success, is by many medical gentlemen considered a procedure of questionable propriety. These doubts of the therapeutic value of this drug arise, in the majority of instances, from the fatality which has attended its use as an anæsthetic agent. But objections are frequently advanced upon the ground that the exhibition of chloroform sometimes fails to relieve insomnia, and the consequent delirium, and that not unfrequently it induces free emesis, in place of acting as a remedy for nausea and vomiting.

It would indeed be strange, if among inebriates, who unfortunately compose a numerous class in every large community, idiosyncrasies were not observed, and if in the treatment of that disease to which they are liable, any proposed remedy should invariably produce the same results; but if in the majority of a given number of cases a decided and beneficial action is obtained, the cause of failure in the minority may as justly be sought in the individual, or in extraneous causes, as in the drug. Thus chloroform, which has been highly considered in the treatment of nausea and vomiting, produced by sea-sickness, pregnancy, and nervous irritation from other causes, may, when containing impurities, only aggravate the disorders for the removal of which it is administered. On the other hand, idiosyncrasies may be combated in vain, since they are not to be overcome; the instances are so well known of certain drugs, harmless to the many, but exercising invariably an unpleasant influence over a few, that any enumeration would be unnecessary. In a somewhat extended experience, in which the remedial power of chloroform has been carefully observed, very few instances have occurred in which its administration caused vomiting; and even in these cases, with but one exception, the same amount having been repeated, after a short interval, was retained, and produced the desired effect. Of the instance in which it became impracticable to continue its employment, the cause was found in an intense repugnance which the patient conceived, and which became so strong, that from that time the ethereal flavor invariab y produced nausea and vomiting.

It may safely be accepted, that an over-dose of chloroform would most likely be quickly ejected by the stomach. To this fact are to be attributed the very few instances on record in which death has resulted from over-doses, which have been taken either by accident or from criminal purposes. Still this proposition must admit of qualification, since chloroform has produced violent poisoning in some cases on record—in a few others, death.

In the successful employment of chloroform as a remedial agent, much stress has been laid, by observers, on the great variations which may be made from a standard dose. A fluid-drachm, which in the majority of adults will procure sleep, being taken as a standard, it may be increased or diminished *pro re nata*; but in those cases which indicate the production of a decided hypnotic effect, it is certainly advisable to bring the patient rapidly under its influence. In fact, it will be found, that among the most frequent causes of failure

in the use of chloroform, are the insufficient doses exhibited, and the length of the interval between them on their repetition.

The impunity with which chloroform may be given in large doses has been frequently illustrated within my observation, and its application has not been confined to the treatment of delirium tremens alone. In a case of epidemic cholera occurring in a delicate female, who was in collapse, pure chloroform, in drachm doses, was four times administered, at intervals of ten minutes, with the most decidedly beneficial results. The cramps, vomiting, and purging were arrested, after which the remedy was repeated in half-drachm doses every thirty minutes, for two hours, when reaction was fully established. But still more encouraging has been my experience of the advantages to be derived from its exhibition in full doses, at the inception of disease; and especially does this refer to the treatment of delirium tremens.

It is imperative that chloroform about to be ingested should be chemically pure; as the employment of a specimen which has been adulterated with ether or alcohol, or one in which decomposition has taken place, or in which the heavy volatile oils are present, will either yield negative results or may be positively injurious. In order to avoid this danger, whenever a doubt exists, the specimen should certainly be subjected to the various tests.

Care should always be taken when about to administer chloroform by the stomach, especially to persons of a delicate organization, that it be suspended or enveloped in some vehicle which will disguise the pungent sweetness of its taste, as from it alone nausea, vomiting, or an intense antipathy may arise. To others less sensitive a small quantity of iced water will be sufficient; for the stimulation of the mouth and fauces, as the remedy passes, is but momentary, not more unpleasant or powerful than the same amount of pure alcohol would be to an uneducated surface; and when it reaches the coats of the stomach, the sensation, being that produced by a diffusible stimulant, is, in the majority of instances, a pleasing one. That pure chloroform cannot long remain inert, when taken into the stomach, will readily be conceived from its physical properties. Impelled by its specific gravity it must pass quickly from the stomach into the intestinal canal, and through its peculiar volatility is soon converted into vapor. These characteristics render its absorption not only more prompt than those of the majority of other remedies, but more certain, even when the vital powers are all but exhausted. The rapid penetration of the densest tissues by chloroform vapor, and its power as an antiseptic, have been established by the experiments of Augend and Robin.

The effect produced by chloroform upon the nervous system can at best be ill defined. That it acts peculiarly for the relief of disordered nerve ganglia; that it diminishes congestion in its varied forms; and that it differs materially in its operation through the stomach, from its action when employed as an anæsthetic through the lungs, is evident, from the results obtained.

Administered to the digestive organs it acts as a diffusible, stimulating hypnic, possessed of diuretic and diaphoretic properties, and when taken in unusual doses, as an inebriant and irritant. Its therapeutic action is peculiarly that of a neurotic, and influenced by the extent to which it is administered, may be employed to rouse the nervous system when depressed, and to tranquillize it when over-excited; or in other words, its contact with the nerve centres is sufficient to restore to them the power of recovering their equilibrium, and of reëstablishing their normal influence over dependent structures. This is shown in delirium tremens, the delirium of fever, insomnia, and diseases of that class, by the natural, not comatose or anæsthetic sleep, which will continue for hours after the quantity introduced through the stomach into the system has been eliminated. Its power is further shown in the cold stage of intermittent fever, and in the various rigors in which the nervous depression, with its distressing symptoms, is relieved, and reaction established. Also in epilepsy, infantile and puerperal convulsions, painful spasmodic affections, and kindred disorders; it is manifested by the rapidity with which the brain recovering from its temporary irritation, the convulsive or spasmodic movements are arrested. But still more striking is the power exerted over congestion, by restoring the tonicity of the blood-vessels, and thus relieving the local hyperæmia.

Such exhibition of chloroform does not, in the vast majority of instances, derange or impair the digestive power; but reversely, its effect, again, by ganglionic influence, is that of a "food tonic," and in certain impaired or depraved conditions of the system, even in those whose chief characteristic is extreme irritability of the stomach. After its exhibition large quantities of concentrated nourishment are eagerly received. This craving for food, or ability to receive, retain, and digest unusual amounts of nourishment, is, in such cases, due to the chloroformic awakening of the great life centres to the requirements of the system, and should not be counteracted by other means than the natural stimulus of the body—*food*.

Perhaps one of the most interesting exhibitions of the power of chloroform is the rapidity with which, acting as a diuretic, it removes bile from the blood and skin. In a case of jaundice, in which the entire surface of the body was tinged, I gave chloroform in ʒ v. doses every three hours. The diuresis was excessive on the second day; the skin and conjunctiva were nearly clean, and by the termination of the third, the elimination was complete. The affinity which exists between chloroform and bile has led the former to be suggested as a test of the presence of the latter.

The experience of such cases indicates that the elimination of ingested chloroform occurs mainly by the kidneys, and that the medium of the lungs and skin is but little employed. This theory is resolving itself into a fact, despite the contrary assertions of *theoretical experimenters*.

Fully satisfied that observation will convince the most sceptical that chloroform may be internally employed, not only without endangering life, but with advantage as a remedial agent, I have ventured to submit to the profession the foregoing remarks upon its internal administration, in a few of the many forms of human suffering which it is most probably destined to relieve.

Early Menstruation.—W. A. Simmons, M.D., in the *Cincinnati Journal of Medicine*, relates the following case: M. F. P., aged eight years, of short stature, fair skin, of nervous-sanguine temperament, commenced to menstruate at the age of seven years and seventeen days, and has had a catamenial discharge regularly every lunar month since that period—one year. The mental and physical signs usual at such times in menstruating women, are well marked. She is rather larger than girls of her age, and usually healthy. The mammæ are developed but slightly more than ordinarily, and no other signs of puberty. They are people in ordinary circumstances, and have not been surfeited with the good things of this world, excepting plenty of outdoor exercise.

REMARKS ON THE TREATMENT OF FRACTURES OF THE PATELLA.

WITH A DESCRIPTION OF THE LATE DR. THOMAS TURNER'S APPARATUS,

By FRANCIS V. WHITE, M.D.,

OF NEW YORK.

(*Continued from page* 200.)

I HAVE consulted the last edition of Prof. F. H. Hamilton's able work,* and find nothing regarding appliances for treating fractured patella, but that is already mentioned. He had seen bony union in two cases. He employs the same dressing as in the edition I have, viz. a single inclined plane, well padded, especially under the knee; bandages the leg and thigh, in part, flexes the body on the thigh to relax quadriceps femoris; applies a compress longitudinally of muslin, one-quarter of an inch thick, breadth of knee, extend ng from four inches above the patella over on the tibia; an assistant approximates fragments, the surgeon secures them with adhesive plaster, two or two and a half inches wide, the length sufficient to pass obliquely on the splint, through the notches, commencing upon the compress partly above and upon the upper fragment, strapping the knee entirely ("imbricating"). The whole extremity is to be bandaged lightly for support. His plane is ingeniously fabricated; the foot piece is arranged by a hook contrivance. The inclination may be varied from six to eighteen inches; the plane is six inches wider than the limb at the knee, and is notched on both sides, four inches below the knee, the object being not to ligate the knee. The best result he gives is a quarter of an inch intersubstance.

I quote from his last edition: "Malgaigne's hooks or clamps I regard as liable to more serious objections, and notwithstanding considerable testimony in their favor, I should be reluctant to recommend them."

I select the following cases from the London *Lancet*, 1852, vol. i., p. 283: An interesting one in Middlesex Hospital, under care of Mr. Shaw. The patient, twelve years previously, was treated in the hospital for fractured left patella, resulting in half an inch intersubstance. A year subsequently he refractured it, submitted to no treatment, and in a few weeks walked. Mr. S. had an apparatus (not described) to protect the joint, which was greatly exposed, from injury, viz., separation of the fragments six inches, extensor muscle atrophied. The same article states that Mr. Adams, at the London Hospital, treated two cases by position, leaving nature to herself. One, a male, was treated less than a month; the other, a female, was treated a little more than a month. The results, firm as usual, separation a quarter of an inch. Mr. Harvey exhibited in 1858 to London Pathological Society, an ununited fracture of the patella. The patient rheumatic and gouty. Death resulted from his condition affecting his ear. The treatment of patella produced rheumatism of his limb. The Society considered that this case proved that a rheumatic, gouty condition opposed union. Mr. Gamgee in the same journal, page 366, says: "The treatment of fracture of the patella was often regarded as very simple, but there were more cases of cripples from fractures of this than from any other bone." The disputed point of bony union is referred to. Two cases are also related, treated by Mr. Cooke, Royal Free Hospital: One, oblique fracture of the patella, dressed a few hours after injury, the fragments widely separated by a figure of eight, starched bandage; result appeared osseous, favored by the speedy dressing. The other case a transverse fracture, dressings the same, time not noted, the result ligamentous. Neither was confined to bed.

Mr. Partridge, in 1861, exhibited to the Pathological Society of London a patella fractured by direct violence; bony union resulting. Autopsy made one year after the fracture. He remarked the scarcity of specimens of osseous union found in the museums of London, there being but two or three. Mr. Brooke mentioned cases of bony union, after violence, resulting from wearing an unyielding splint several months, in the popliteal space, after leaving the hospital.

A case of transverse fracture, of a pregnant woman, coaptated and held in position twenty-four hours afterwards, by a posterior splint from the middle of the thigh to the calf, in which were hooks for extension and counter-extension, is reported in Lancet for 1861, p. 484. In six weeks it appeared perfectly united. A posterior gutta-percha splint was fixed, to favor consolidation and prevent too extended movement. The seventh week she had typhoid fever, pneumonia following, and a miscarriage on eighth day of fever. Died on the ninth day. During delirium was uncontrollable; flexed her knee; twenty-eight hours before death the fracture gaped fully an inch. Necropsy revealed suppuration of the new tissue of the patella.

Mr. Wilkinson King* described a patella broken transversely, with osseous union.

Dr. T. S. Kirkbride,† late resident physician of Pennsylvania Hospital, reports six cases of fractured patella, during two years he was there. In the first and third cases, females, the result was rather more than a quarter of an inch shortening. She returned with fracture of the other patella in about six months. The result one-eighth of an inch, the upper fragment a little depressed. Second case, the union perfect, no separation appreciable. Fourth case, no separation except the small fragment a little depressed. The fifth a difficult case; had *mania a potu;* the result less than a quarter of an inch; he would not submit to advice; accidentally refractured it; separation between two and three inches, intersubstance. He returned to the hospital for treatment. Sixth case, a compound fracture, was under treatment. No particular treatment noticed.

Reports of surgical practice.‡—Six cases of fractured patella, including two refractures; of the latter, one appears to have been osseous. The patient declared there was no line of fracture. On examination, the dresser, Mr. Pern, heard crepitus. The mode of treatment of ordinary fracture of the patella, at St. Thomas's, is as follows: After the subsidence of any existing synovitis, adapt leather or gutta-percha cap splint, cut out, to receive the fragments, coaptated by horse-shoe shaped straps. A Liston splint applied, limb raised at the foot. "In some cases only the long pieces of strapping running from each side of the skin to above the upper fragment, and a shorter piece pulling upwards the lower, are made use of. M. Malgaigne's hooks do not find favor at St. Thomas's."

Ring appliance.§—Dr. W. A. Gibson (*St. Louis Med. and Surg. Jour.*, Oct., 1866) reports a case of transverse fracture of the patella. He measured sound patella, for the pattern of a ring, allowing for padding with cotton, which was cut in strips, and held by a bandage around the ring. He sewed strips of muslin to each side, placed a well padded posterior splint, twenty-four inches long, secured by a bandage, at the lower and upper ends, lightly applied; approximated the frag-

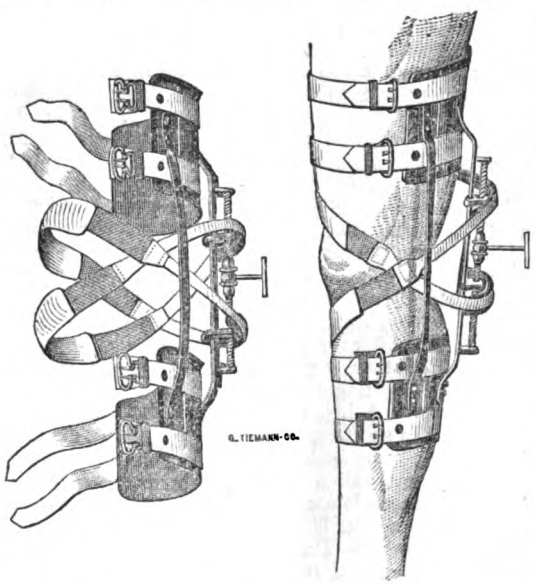
ments, applied the ring over, tied the strips over the splint, securing the ring in its place, and keeping the fragments in apposition, giving the best chance for osseous union; removed the dressing in thirty days; made passive motion; found bony union complete. June 15th, had very good use of the limb. He says: "The appliance did not give the patient the least pain, and there was no interruption of the circulation by the bandages. It was impossible in this case for the patella to escape from the ring, but possibly in some cases, as of women where there is a good deal of adipose tissue, and but little prominence of the patella, it may not be so easy to apply the ring; but I am persuaded that it will give entire satisfaction in all cases. I claim, by the application of the ring, to have reduced one of the ugliest fractures of the human frame to one of the simplest for treatment."

Prof. Paul F. Eve, Nashville (*Nashville Jour. Med. and Surg.*, Feb., 1867), records two cases successfully treated by the above plan.

I discovered in my researches that the literature of our profession was very barren of subsequent conditions of fractured patella, say a year or more, after treatment, both as applicable to the living and dead.

From the preceding investigation and the observations already made, I think myself not presumptuous in concluding, that it is within our power to have osseous union in ordinary fractures of the patella, if the fragments can be closely coaptated, even if the aponeurosis is ruptured. As near a result should be attained by art as possible, to the preceding natural condition, the work of the great Architect.

I believe the invention of the late Dr. Thomas Turner, Resident Physician to Kings Co. Hospital, L. I., New York, is the appliance to accomplish the above.



The cut represents its mechanism. The apparatus, manufactured by Tiemann & Co., New York, consists of thigh and leg-pieces of sheet-iron, with two buckled straps attached to each, united by two lateral bars and one posterior bar of steel. To the posterior bar are two troughs (part of a circle), on a double reversed screw, and by turning the key in opposite directions the troughs separate or approach each other. The apparatus being japanned, is always ready for new cases when cleaned. The apparatus should be applied in simple fractures as soon as possible; but if, in the opinion of the surgeon, it would aggravate existing inflammation, thereby jeopardizing the joint, it could be applied as a posterior splint, without using the coapting appliances, until antiphlogistic measures make it safe. The apparatus, to be applied properly, should be well padded with flannel or other material, for protecting thigh and leg from the splint and straps, quadriceps femoris should be relaxed, the limb held by the thigh portion, and buckled; also buckle the leg portion. Use an anæsthetic if necessary. First fix the lower fragment, by drawing it up, smoothing the integuments down; this being held by an assistant, the surgeon applies a strip of adhesive plaster, of sufficient width to hold the fragment, and overlaps it sufficiently to prevent any tilting up, passes the free ends of the adhesive plaster around the upper trough, crosses them and applies them to the skin. The upper fragment being coaptated, the integuments being smoothed up, a similar piece of plaster is applied around the lower trough as around the lower fragment. Interpose something where the plasters cross each other, to prevent their sticking together.

For firmness use double strips of plaster. Snip the upper edge of the upper plaster; thus a rounded edge instead of a cutting edge will be presented to the integuments, avoiding in a degree excoriation.

The next case of simple transverse fracture of the patella I shall have to treat, I shall use a part adhesive plaster and rubber coapting appliance, viz. taking measurement and having rubber tubing of sufficient length, say half the distance, with rings affixed to extremities, and the other half adhesive plaster. The adhesive plaster having been passed through one ring on one side and fixed, the strap being applied to patella as previously stated, is passed with the tubing around the trough, the free end of the plaster being passed through the other ring and made adherent, marking the plaster to note any slipping. If there should be a V-tilting, a compress can be applied over the patella. If position is necessary, a pillow can be placed under the leg. Place a pad in popliteal space if necessary. As the dressing may loosen, move the screw, and thereby separate the troughs, which will tighten the dressings. Apply new dressing when necessary. If there is much inflammation, apply bags of ice (of bladder or oil silk) intermittingly every fifteen minutes over the dressings and joints, thereby keeping the dressings dry. The apparatus should remain applied thirty or forty days; slight passive motion should be commenced on third or fourth week, the patella being held, although I deem it hardly necessary, as I noticed in the treatment of my case, that after the application of the apparatus, slight movement could be made without strain upon the patella. When new dressings are applied, the patella being held, cautious passive motion may be made until the apparatus is permanently removed.

After the apparatus is removed, the patient, to favor consolidation, should wear something to prevent too much use of the patella—say for four or six months, viz. elastic knee-cap, with a ring arrangement over patella, or posteriorly a piece of gutta-percha or leather strapped above or below the joint, either of which being softened by warm water, can be applied, and allow of a certain flexion. Passive motion can be occasionally made, but not extreme under six months.

The advantages of the apparatus are: the ease of its application; efficiency indicated by the combining of a posterior splint with coapting means. The knee-joint is exposed to the view of the surgeon and patient, thereby saving anxiety. Without further expatiating, I would state I would not dare to use any other appliance that I am acquainted with; and I think I am

sustained in this assertion by the letters I have the honor to possess of distinguished gentlemen of our profession, and the result of my own case. It may not be inappropriate to state that I had an interview with Dr. Turner in the summer of 1860. I congratulated him on his benefaction to our profession and humanity. I remarked the trouble and time I expended in the treatment of fractured patella, when house-surgeon in Bellevue Hospital in 1856–1857, by the single inclined plane and coapting compresses, bandaging the whole, etc.; whereas, if I had had his appliance, I could have saved time, and had the best of results.

Dr. T. informed me that his intention was, after danger to the joint was over, to allow the patient to be up and attend to business with the apparatus on, thus allowing nature to repair the injury. He showed me the original apparatus which he fabricated for a poor fellow, with fractures of both patellæ, of whom he made a nurse, and who was able in a short time to walk about, resulting in coaptation. I suggested to the doctor the propriety of introducing his apparatus to the profession immediately. He thought it prudent not to, until by experience he could improve it.

I asked his permission to allow me to do so. He acquiesced, promising to write a paper subsequently. On consulting a valued friend in our profession, I was advised not to do so until I could present at least six cases in which it had been used. For this and for other reasons unnecessary to mention, it has been delayed until the present.

During the last few years the merits of Dr. Turner's apparatus have been thoroughly tested by not a few eminent surgeons of New York and vicinity, all of whom speak of it in the highest terms of commendation. Among these gentlemen I may mention Drs. J. M. Carnochan, W. Detmold, J. C. Hutchison, G. Cochran, R. C. Styles, and E. C. Mundy.

In conclusion I beg leave to detail the following interesting case occurring in my practice, in which the apparatus was satisfactorily used.

Mrs. R., Houston street, healthy, fleshy, aged 41, received a transverse fracture of her left patella, about its middle, July 11, 1860, by muscular action, in going up her stoop, her left foot having slipped on the first step. She fell in a sitting posture.

I placed the whole extremity in position on a well padded, inclined plane, and applied lotions. On my evening visit, the patient complaining of an unendurable burning sensation about her foot, I removed the dressings, leaving nature untrammelled in position.

I applied Dr. Turner's apparatus, the 14th instant, continuing the lotions. On the 16th, dressings being loose, I reapplied them. Stopped the lotions. I dressed the fracture subsequently as was indicated. I used double straps of adhesive plaster about two inches wide, and of sufficient length to cross each other on the troughs, and brought up the sides, marking the ends, to note slipping. The upper strap produced a little excoriation, which was relieved at the suggestion of my patient, by snipping the edge of the plaster, which, on application, presented a rounded surface; even afterwards I was somewhat troubled; but, by varying the pressure, underlaying with a small piece of lint, it did well. Placed a pad in the popliteal space, for support. I tried straps of adhesive flannel, they slipped, and crescentic pads of cork covered with shammy; they produced pain. I used the screw as indicated. On September 8th, permitted my patient to walk about her room, with apparatus on; the action produced inflammation of the integuments, where the straps were applied. September 21st, removed the apparatus, after a treatment of sixty-nine days. My object was to obtain bony union. I cautiously made passive motion first about the third week; afterwards, when I applied new dressings, I noticed the apparatus would allow some movement of the joint, not enough, though, to put strain on the ligament. After the removal of the apparatus, I increased my passive motion. Had the patient occasionally sit on a table, and swing the leg. I did not apply any protection to the patella, either knee-cap or splint, in popliteal space, which I now regret, as nature might in six months have consolidated the union. November 28th, I made my last professional visit. At that time the patella appeared united by bone, as I thought. The functions of the joint were restored. My case tested the apparatus, there being a large thigh and leg and small patella, about half an inch of integument, fascia, etc., over the patella (judging from other patellæ), with the swelling, making a thickness of over an inch, through which I had to coaptate the fragments. I believe I could not have treated her with any other apparatus with a shadow of success.

I made an examination of the patella, April 22nd, 1867. Found an intersubstance of about half an inch. Integuments over patella movable, but thicker than over opposite patella. She has perfect use of her limb, with the exception of going down stairs; notices a feeling of lack of support.

80 First Street.

CASE OF

ENTIRE ABSENCE OF ANUS WITH RECTO-VAGINAL FISTULA.

SUCCESSFULLY TREATED BY

HOWARD PINKNEY, M.D.,

SURGEON TO OUT-DOOR DEPARTMENT BELLEVUE HOSPITAL.

Corinna P—, aged 8 months, was first seen by me 21st November, 1866. The infant was exceedingly small, very thin, and had a sallow unhealthy appearance of the skin, and very fretful. Mother states that the child has never had a free discharge from its bowels, and that at the present time it is only after severe straining efforts in which the little sufferer turns almost black in the face, that a small thread-like portion of fæcal matter is forced through the vagina. She also says that since the birth of the child she has never been able to keep its extremities warm.

On examination I found an entire absence of anything that resembled an anus. The skin between the ischiatic tuberosities, vagina, and coccyx, was distended and smooth, with the exception of a raised ridge or raphé, extending from the posterior fourchette to the coccyx. On examining the vagina I found a small opening (sufficient only to admit a large-sized probe) on the posterior wall of the vagina, and about a quarter of an inch from its orifice, communicating with the rectum, and through which fæcal matter was forced during the straining efforts. Examining the abdomen, I found it very much swollen and distended.

As the child was rapidly failing, and as the mother and friends had given up all hopes of its recovery, I advised an immediate operation as the only means of relieving the little patient. The mother consented after a few days, and on November 28, assisted by Dr. R. F. Weir, I operated as follows: The child being placed on the lap of an assistant, was brought under the influence of chloroform by Dr. Weir, and being then placed in the position for lithotomy, a probe was introduced through the opening and directed towards the perineum. I then made an incision from a point a few lines posterior to the fourchette to near the point of the coccyx in

the median line, and carefully dissected inwards in this line until I came to the rectum, which was readily distinguished, as it was greatly distended by impacted fæcal matter. The incision posteriorly extended a little more than an inch in depth; anteriorly 4 or 5 lines. The probe that was passed through the opening was forced down, and could be readily felt at the bottom of the sac. Opening the gut upon the point of the probe, I introduced a director bent nearly at right angles, and then by means of a probe-pointed bistoury enlarged the opening to the size of the external wound. As soon as the gut was exposed straining efforts commenced, which continued after it was opened; but no fæcal matter came away, although it could be readily seen impacted there in large quantity. By means of the handle of a spoon and of a scalpel, I was enabled to dig out a large quantity of hardened fæces, when a large quantity of consistent fæces came away, taking the form of the external opening and being at least an inch in diameter. After carefully washing out the bowels with an injection of warm water, I brought down the edges of the divided intestine, and united them to the margin of the external wound by means of silver sutures; then placing a pledget of oiled lin tin the opening to keep the surfaces from uniting, the operation was completed.

The next day, on visiting my little patient, I found her looking much brighter than I had ever seen her before. She had slept well, and had had one or two free movements from the bowels. Examining the wound I found the sutures through the intestine torn out, and the intestine retracted within the wound. I made no attempt to draw it down, but merely removed the sutures, and distended the opening (which showed a tendency to unite) by means of my finger and the blades of a dressing forceps, after which, I renewed the pledget of lint. This treatment of dilatation by means of the finger and forceps, with the occasional use of a rectal bougie, was continued almost daily up to Dec. 14, when the wound was entirely healed, and was lined by a smooth and shining membrane. This opening was sufficiently large to admit a number 11 rectal bougie. There seemed also to be a tolerably well formed sphincter developed, which kept the external opening closed, and would grasp the finger when introduced. No attempt was made to close the recto-vaginal opening, except by cauterization of its edges with nitrate of silver, hoping that it might possibly close of itself, or in case it did not, intending to operate at some future time.

Old Folks.—The St. Louis *Medical Reporter* speaking of "Old Folks," says: The entire number of persons who, according to the census, have attained the great age of 100 years and upwards, is probably larger than most of our readers would guess. It is just 1,200; of these there are white, 440; black, 688; mulattoes, 56; Indians, 26. Women attain a high longevity in greater numbers than men, and black people than white. The oldest persons are a white woman in South Carolina, and an Indian woman in California, aged 140 years. The oldest blacks, two males and two females, are 130 years. In proportion to numbers, twelve times as many blacks as whites exceed a hundred years of age. By the best calculations made, it is ascertained that the average duration of human life is greater in the United States than in any other nation.

Milk in the Breast of a Male Infant.—Mr. Owens reports a case in a recent number of the *Lancet*, of a male child, 9 days old, from each of the breasts of whom he obtained half a drachm of milk.

WITH REMARKS

By PROF. FRANK H. HAMILTON, M.D.,

BEFORE THE CLASS OF '65—'66 OF

BELLEVUE HOSPITAL MEDICAL COLLEGE.

(*Continued from page* 154.)

Gentlemen—In connection with my account of a single fissure, I ought to describe to you a method which I have devised and practised for the cure of those simple indentations of the lip which are sometimes congenital, but much more often the result of a partial failure in the attempt to close a harelip.

When, for example, the fissure only extends up into the lip two, three, or four lines, I proceed as follows:—

With a narrow, sharp-pointed, straight bistoury, I transfix the lip at a point about three lines above the apex of the fissure, and proceed to cut downwards and outwards until within three or four lines of the free border of the lip. Carrying my knife back to the point at which the incision commenced, I cut downwards and outwards again, parallel to the opposite margin of the fissure, to within three or four lines of the free margin of the lip. The triangular loop thus formed is at once forced downwards, and the raw and opposing edges of the fissure brought snugly in contact by one or two sutures.

If the fissure was pretty deep, the loop thrown down will be long, and will require the support of a single fine suture to retain it in place; and even then it will hang down very obtrusively; but by the gradual contraction of its tissue, and perhaps in part by ulceration, it will eventually assume a very natural appearance.

If, however, the fissure was not deep, the loop will take care of itself, and the result will be a perfect restoration of the line of the lip.

You must not omit, gentlemen, to apply the adhesive plasters in this case any more than in a case of complete fissure; nor to extend them well down, so as to completely cover in the lower margin of the upper lip. This measure I regard as of great importance in its bearings upon your complete success.

DOUBLE HARELIP, COMPLICATED WITH FISSURE OF THE BONES, ETC.

It is very seldom that we meet with double harelip not associated with fissure of the bones. This variety of harelip (with fissure of the bones) is found to exist in two principal forms:

First, That in which the central piece of alveolus occupies its normal position; that is to say, is situated in the line of the alveolar arcade, and in which case it is, in general, pretty well covered in front by integument. This central piece of integument may be either quadrilateral or nearly triangular, with its apex directed downwards.

My method of operating in these cases is the same as in single harelip, with only such few points of difference as the peculiarities of the deformity will render necessary.

The central piece is first freshened, or excised freely, on its two margins down to the alveoli; but not dissected up or detached in any degree from the alveoli. This part of the operation ought to be made first, because the principal source of the hæmorrhage is from the second or next step of the operation.

If the central piece is very short, whatever its form may be, it must be made into a triangular form by incisions, with its apex directed downwards.

The outer margins of each fissure are next to be dissected from the bone, and usually to a point fairly up underneath the alæ. These margins are then cut straight and freely with very strong scissors.

A large straight needle, armed with a strong silk ligature, is now made to enter near the outer margin of the ala, upon one side; it is then carried across, in front of the central piece of alveolus, beneath the base of the integument covering this piece, and brought out at a corresponding point under the opposite ala. This suture is then tied firmly over the central piece of integument, having previously protected the integument by a small roll of patent lint. With this precaution there is no danger of strangulating the central piece.

A second suture is now passed near the lower margin of the fissures in the same manner, only observing the rules laid down when speaking of single fissures, namely, to introduce the needle far from the incised margin and at the junction, or immediately above the junction of the vermilion border with the skin; and to bring the needle out at a corresponding point on the opposite side.

The second suture is now closed; and in a similar manner a third, intermediate between the two, may be introduced if it is thought necessary. The dressing is completed by applying the adhesive straps as already described.

You will be surprised, gentlemen, to find how wide a chasm you can in this way close up; and if the operation is carefully and thoroughly performed, there is but little if any more danger that it will give way, or refuse to unite, than in a simple and narrow fissure.

It seems to me absurd to talk of making this operation at "two times," as some have done—that is, of closing first one side, and when this has healed, proceeding to close the other. It can always be done more easily, and, as I think, more perfectly at one operation.

The second form of double, complicated harelip is that in which the central piece of alveolus is not on a line with the alveolar arcade, but is projected more or less forwards, in some cases standing directly forwards, and appearing as if it was a prolongation of the nose.

In order to comprehend the surgical treatment of this class of cases, it will be necessary to say a few words in relation to the anatomy of this central piece.

The alveolar, or dental arcade of the upper jaw, is formed from four centres of ossification. The two lateral portions, including the sockets of all the teeth except the incisors, are formed each from a single point of ossification. The central portion, including the sockets of the four incisors, is formed also from two separate points, which, in the process of growth, speedily come in contact by their opposing surfaces along the median line, but do not actually blend with each other; consequently, even in adult life, the two upper maxillary bones can generally be easily separated between the central incisors. Where the two halves of the incisive portion of the dental arcade lie in contact, two thin plates are finally projected upwards, one from each margin to form a junction with the triangular cartilage and the vomer; the whole of which together forms the septum nasi. The anterior extremity of these parallel plates is known to anatomists as the anterior nasal spine. How complete is the union which finally takes place between these thin, short, vertical plates on the one hand, and the vomer and cartilage on the other, I cannot positively say; but they are easily separated by maceration. It is my opinion that in early life the union is very incomplete; and that at the period of two or three years, that process which unites the vomer to the incisive portion is very narrow and feeble. So that, in forcing the central portion back, by pressure applied in front, the septum would be more likely to be bent or twisted than broken.

Upon the anterior and lower margin of this septum is situated a bulbous looking expansion; which is that portion of the alveolar arcade containing the germs of the four incisors.

Several surgical writers have spoken of this central portion as containing two teeth, or their gums. In all the specimens examined by us it has contained four teeth, or their rudiments; and of these two have generally been found on the outer margins of the central piece, and not upon its lower margin; so that, in the progress of their development, these teeth have stood directly outwards laterally—while the two remaining teeth were directly forwards, or forwards and downwards. I do not think, therefore, that it is in general advisable to attempt to save the central piece. The teeth which it contains will not grow harmoniously; and its pedicle or that process which connects it with the septum nasi, and which constitutes its only basis of support, is too feeble to make it useful. I have in most cases cut it away. In this case the operation must be made at three times, as follows.

First, the central piece of integument, which I have never found of sufficient length to serve any purpose in the formation of the upper lip, must be dissected up from the alveoli, and left attached to the end of the nose, to be used at a subsequent period in the formation of a columna nasi. At the same time, the pedicle which supports the central piece of bone is to be divided with a pair of sharp bone cutters, or with a strong pair of scissors. In dividing these, great care must be used to make the section as far forward as possible. If too much of septum is removed, the nose will have an unpleasant cavernous look. It is better to cut away too little than too much.

The bleeding from the artery of the septum I have always found troublesome. It is generally impossible to secure the artery with a ligature; but pressure with the finger continued a few minutes, will often succeed in arresting the bleeding. If necessary we may place upon it a pledget of lint, and secure it in place with an adhesive strap laid across the face. This completes the first operation.

The *second* operation cannot be made safely until after the lapse of one or two months. This is simply an operation for the closure of the fissure, and the several steps of the procedure will differ in no material respect from the operation already described for simple harelip. It is not well to attempt to make the columna at this time.

The *third* operation is not to be undertaken within less than three months after the last operation, for the reason that any lesion of the new lip, along the median line where it has but recently united, is likely to result in a destructive ulceration; and the columna cannot be made fast below to the lip without causing such a lesion.

The operation is as follows. The posterior surface of the central piece is freshened, and the two lateral surfaces, with the lower end, cut into shape, leaving it if possible about as wide as you desire the columna to be when the wounds have healed. The anterior surface of the bony septum is next freshened by scraping it with the edge of a knife; a point at the base of the lip is made raw; the lower extremity of the central piece is then fastened by a delicate suture to the upper lip, in such a manner as the peculiarities of the case and your own ingenuity will suggest. In order

1

to assist the union of the columna to the septum, a small pledget of lint covered with cerate, should be laid against the front of the columna, and secured in place by adhesive plaster bands. The subsequent dressings and management of the case must be left to the judgment of the surgeon. Beyond these, no more precise rules can be given.

After the cure is complete a good dentist may supply the deficient teeth and alveoli; and he may improve greatly the form of the upper lip, giving it proper support from behind. In some cases it is better that the teeth should have been fitted and worn some time before completing the formation of the columna.

Reports of Hospitals.

BELLEVUE HOSPITAL.

CASES OF ABSCESS FROM PNEUMONIA OF LEFT LUNG.

By DR. LEWIS A. SAYRE,

PROF. OF ORTHOPŒDIC SURGERY AT BELLEVUE MEDICAL COLLEGE.

John Anderson, æt. 48, butcher; three years ago first had pneumonia of left lung; since which time he has coughed more or less, and expectorated freely. Three months ago the expectoration entirely ceased, and at that time he first noticed a small tumor in its present position over the junction of the last dorsal and first lumbar vertebræ. He states that a short time before the appearance of this tumor he felt pain over the left lung, which seemed to work around until it became seated in the present position of the tumor. He has lateral curvature of the spine, and a slight angular curvature in the dorsal vertebræ; though no history of disease of the vertebræ can be elicited, nor any signs of a still existing disease discovered.

The tumor rises abruptly on the left side of the spinal column, about four inches, and extends over to the posterior superior crest of the ilium, being 22½ inches in circumference, 10 in transverse, and 11 in longitudinal diameter. The integument covering it is somewhat discolored and quite tense. By pressure, the tumor may be partially emptied; and is again filled by allowing the patient to cough. The distance from the sternum over the left nipple to the vertebral column is four inches less than that over the right nipple. The ribs on the left side incline downwards, and overlap. There is indistinct respiratory murmur, and dulness on percussion over the greater part of the left lung, showing probable infiltration; but over a small portion near the wall there are signs of a cavity. It is impossible for him to take a long breath.

Operation.—An exploring needle introduced into the most dependent portion of the tumor, showed it to be filled with pus and serum. On being opened it discharged three pints. The opening was then closed by adhesive straps, and a bandage applied. After the operation there was an increased resonance on percussion, the patient breathed much more easily, and could take a full inspiration. In three days after this operation the abscess began to fill again, and was again opened, when it discharged fourteen ounces of pus and serum. The patient is now, two weeks after the operation, doing well, walking and riding about.

Case 2.—W. W., æt. 10; presented all the symptoms of pneumonia, with free expectoration. He remained in this condition for about two months, gradually sinking, with no abatement of the cough, but increase of expectoration, and constant pain in the left side. About this time the left side began to dilate sensibly, and gave a dull sound on percussion over nearly its whole extent. The respiration was almost inaudible, and the heart appears to the right of the sternum, with its apex pulsating near the ensiform cartilage, showing that effusion had taken place into the cavity of the pleura. The expectoration was checked for a few days, as the effusion went on in the pleura; but in a short time, when the side became distended, and the cavity appeared full, it became as free as before; leading to the belief that ulceration had taken place between the abscess in the lung and the cavity of the pleura. The patient was much prostrated. He remained in this condition six weeks, at which time pain in the side increased; a pulsating tumor began to make its appearance between the cartilages of the third and fourth ribs, near the sternum, simulating an aneurism so much that upon consultation an operation was refused. The tumor began to soften, and in two months after its appearance it ulcerated and discharged a quart of very offensive pus.

The opening was dilated, and the discharge continued very free, and *the expectoration ceased entirely*, the bowels became regular, the anasarca disappeared, and, in a word, all his symptoms were very much improved. He was placed upon supporting treatment. He continued improving for two weeks, when the opening in the chest became closed, and the *expectoration returned as free as at first, and of precisely the same nature as that discharged by the external opening.* Then fever returned with loss of appetite, and I was called again to see him. I opened the wound, and discharged nearly a quart of pus. The *expectoration ceased again entirely*, and a discharge of the same nature continued through the external opening, showing that ulceration had taken place between the pleura pulmonalis and an abscess in the lung, communicating with the bronchia; and when the ulceration had taken place in the pleura pulmonalis, the matter in the abscess was discharged into the cavity of the pleura, which accounted for the check in the expectoration during the filling of that cavity, and its return when the side became fully distended. The ulceration continued on through the pleura costalis, intercostal muscles and integuments, at the *superior* instead of the *inferior* and *most dependent* part, as we generally find it The heart being pressed out of its normal position by the presence of the fluid, brought the arch of the aorta directly under the tumor, which accounted for its strong pulsations, and caused the difficulty in its diagnosis.

The discharge continued free for two or three months, but gradually subsided, and in seven months from the first discharge it had healed entirely; leaving him much deformed, the circumference of the left measuring several inches less than the right side. Respiration could not be heard over the left side; but there was a blowing sound, which, however, gradually gave way to the natural murmur. The patient has now assumed nearly the natural murmur. He now enjoys perfect health.

From the time of the operation the child rapidly improved in health and strength, became cheerful and playful, and the sallow and unhealthy appearance of its face was changed to a healthy and even a ruddy glow.

I have related this case, not because of any particular difficulty experienced in operating or because of anything original in the modus operandi, but to show the rapid improvement which followed the operation, the great relief afforded by it, and the necessity of operating in similar cases as soon as the bowels become at all constipated. So long as the contents of the bowels remain fluid (which they did in the case above related for the first four or five months) little difficulty and suffering are experienced; but just so soon as they become

hardened, so soon do ineffectual efforts commence, the bowels gradually fill up with fæces and gas, digestion, circulation and respiration are interfered with, and the sufferings of the patient are gradually aggravated until either relieved by the surgeon or death.

Progress of Medical Science.

Death by Drowning.—In the January number of the *Union Médicale de la Gironde*, published at Bordeaux, is an interesting paper by Prof. J. E. Petrequin, of Lyons, in which are expressed some original views concerning this subject. Opportunities were enjoyed by this gentleman, in 1864, to study it in a special manner. His experience led him to the adoption of a classification, based upon a diagnosis of the physiological and pathological conditions which immediately precede and accompany asphyxia by drowning. Cerebral apoplexy, as a concomitant pathological state, denied by Orfila, and admitted by Devergie, he asserts to be one of the distinguishing forms of death by submersion. The symptoms of those who are submerged during repletion of the stomach, as after a copious repast, belong to his second class, and especially call for the evacuation of that cavity. His third class refers to those who, from fright, faint at the moment of being submerged. His fourth class comprises that condition described by most authors as characterizing death by drowning, and in which therapeutic means are designed especially and immediately to re-establish the respiratory function.

The Diagnosis of Indurated Chancre.—Dr. Lagneau offers some judicious remarks in the *Gazette Hebdomadaire*, of the 8th March, on the subject of simple and infecting or indurated chancres. The period of incubation of the indurated chancre may be less or greater than fifteen to twenty-five days. Between the perfectly soft and well marked indurated chancre, there are many intermediate degrees, which practically do not permit a positive diagnosis of the specific character of the sore. There are other reflections of interest and practical importance noted in Dr. Lagneau's communication, which is an excellent summary of the different opinions on this matter, collected from periodical publications.

Explanation of the Favorable Effect of Iridectomy in Acute Glaucoma, by Fano.—It is generally accepted that glaucoma is an irido-choroiditis, with hypersecretion of the fluids of the eye, by means of which latter a compression of the retina with consecutive anæsthesia of this membrane occurs. The excision of a piece of iris is said, by diminishing the secreting surface, to relax the tension and restore the normal pressure. In opposing this view, the author calls attention to the changes in the vitreous in the beginning of acute glaucoma, which become a physical hindrance to vision. An acute œdema of the conjunctiva is also observed in some cases, which indicates disturbance in the venous system. The vitreous, having no vessels, is nourished by imbibition from the arteries of the choroid, of the ciliary processes and of the retina, and the diminished transparency of these parts shows a change in the circulation of the vessels. If we consider, now, the rapid appearance of this symptom, with the coincidence of severe pain, as is observed in senile gangrene, may we not consider glaucoma as an inflammation of the arterial system of the eye? Iridectomy always (?) causes a hæmorrhage into the anterior chamber, whereby a direct depletion of the inflamed vessels occurs. This may be the proper explanation for the favorable result from iridectomy.—*L' Union Médicale, Memorabilien Heilbronn.*

Alterative Laxative Pill.—Dr. Gilman Davies (*Boston Med. and Surg. Jour.*) extols the virtues of a laxative pill prepared after the following formula: ℞ Pil. Aloin. c. Ferro gr. xxiv, Ext. Nucis Vom. alc., gr. vi., Pulv. Ipecac., gr. vi. *M.* Fiant pil. No. xviii. Dose, a single pill. The pills are small, about half the usual pill-size. "One of these, taken each night, keeps the bowels in a regular condition, operating without pain, and of course chiefly by its tonic power; while the whole system gently but surely feels the strengthening effect of the iron and nux vomica."

Cutaneous Absorption.—M. Charles Hoffmann has laid before the Paris Academy of Science a paper on this subject. His experiments have been made on digitalis, iodide of potassium, and chloride of sodium. He comes to the following conclusions. 1. Chemical and other agents, dissolved in water, penetrate slowly but obviously into the animal economy, by the external tegument, and it is only when the blood and other fluids are saturated by them that the organism expels them. 2. All medicaments are not absorbed in the same degree. 3. The contradictory results hitherto obtained were only due to the insufficient length of the time devoted to the experiments.—*British Med. Jour.*

Arsenic in Prostatitis.—Dr. T. B. Buchanan, of Nashville, reports that some time since he gave a patient Fowler's Solution of Arsenic, for sycosis menti; after using it a week, the remedy was discontinued and the application of sulphite of soda relieved the case. The patient had been suffering for ten years with chronic prostatitis, caused by a protracted attack of gonorrhœa, rendering him miserable and at times impotent. Nearly every remedy that has been recommended by the profession had been used in his case, but with little benefit. "To the delight of the patient and my utter astonishment," says he, "he is now perfectly well, and has been for more than a month." Since arsenic has proved beneficial in hæmorrhoids, might it not have relieved the prostatitis, as the hæmorrhoidal and prostatic plexus of veins are intimately commingled? Arsenic probably effects its cure upon the skin in disease, and that condition of the spleen and liver, after intermittents of long standing, not by any specific action upon the blood, but upon the vessels themselves, thereby equalizing the circulation and rendering it normal.—Paul L. Eve.—*Nashville Journal of Medicine and Surgery.*

Gun-shot Wounds uniting by first intention.—Dr. J. W. Thompson, in the *Nashville Journal of Medicine and Surgery*, gives four instances of wounds healing without suppurating. Three were in hospital practice, and one was in a private patient. Two of the hospital cases were long flesh wounds, and all would be classed as deep-seated. Two were made by minié balls, the third by a small round ball. There was no swelling or redness following the wounds in the hospital cases. A small scab formed over the entrances and exits, when they healed. As regards the case in private practice, the ball was discharged from a Derringer pistol, entered beneath the inferior maxillary bone on the left side, and lodged near the corresponding submaxillary gland on the other side. This patient recovered in a reasonable time. The wound now gives him no trouble.

The Human Bite Poisonous.—A singular occurrence has just happened in Arth, France. A Lieutenant Felchin was some time ago bitten in the thumb by a man named Muller; but he thought nothing of the wound, and went next day a journey on his private affairs. On reaching the Balse, he found his hand and arm began to swell, and a medical man declared that

the case was one of poisoning by a human bite. He at once returned home in haste, but refused to have the arm amputated. The inflammation increased frightfully, and he died some days after in horrible suffering. —*Nashville Journal of Medicine and Surgery.*

PERCHLORIDE OF IRON AS A HÆMOSTATIC.—The *Antwerp Journal* states that perchloride of iron combined with collodion, is a good hæmostatic in case of wounds, the bites of leeches, &c. To prepare it, one part of crystallized perchloride of iron is mixed with six parts of collodion. The iron should be added gradually and with care, otherwise such a quantity of heat will be generated as to cause the collodion to boil. The composition, when well made, is of a yellowish-red color, perfectly limpid, and produces on the skin a yellow pellicle, which retains great elasticity.—*Nashville Medical and Surgical Journal.*

ETHER SPRAY IN STRANGULATED HERNIA.—Dr. John Borelay reports in the *British Medical Journal*, a case of strangulated hernia, in which reduction was accomplished after the use of ether spray. The pain induced after the most gentle handling of the hernial tumor was so intense, that Dr. B. had to desist from taxis. Having with him Richardson's Ether Spray Apparatus, and thinking it might be useful in lieu of ice, it was determined to invert the patient, apply the ether spray short of freezing the skin, then to attempt the reduction, and if failure was the result, to operate with the knife. The head and shoulders then being supported on the floor by some pillows, and the buttocks raised as much as possible against an inclined plane, extemporized by an inverted bedroom chair, the ether spray was directed in the usual way on the swelling, for about forty seconds, when a minute spot appeared white. The spray was at once removed, and on applying the fingers of the left hand on the swelling for about ten seconds, accompanied by the most trifling pressure, the hernia was reduced, to the great delight and satisfaction of all. The man made a first-rate recovery.—*Medical and Surgical Reporter.*

QUININE AS A PREVENTIVE OF MALARIAL FEVER.—Dr. O. White, in a report to Gen. Ripley (of the late Confederacy) in regard to the "health of several encampments on James's Island and in St. Andrew's Parish, and also upon the prophylactic virtues of quinine against country fever," says: "Of the prophylactic virtues of quinine against malarial impressions, it may be asserted with confidence, that fortified with that wonderful drug none need fear venturing at any time into the heart of our low-lands in summer—inhaling with impunity its deadly miasm. Abundance of evidence can be brought to prove this assertion. This reliance in its virtue to resist malarial disease is unlimited. Many have lived protected by it for ten years or more, spending summer after summer in the sickliest regions."

Dr. Barker and the Government members of the Niger expedition, being abundantly supplied with quinine, encamped with safety upon the banks of that fatal river for over twelve months.

The African explorers under Dr. Livingston, were preserved entirely free from the pernicious fevers of the climate, by the habitual use of quinine. Further evidence of the prophylactic virtues of quinine has also been afforded to many of the officers of the British Government stationed on the coast of Africa, in reports from the various stations collected and arranged by Dr. Alex. Bryson. The British steamer *Eliaia* steamed up the river Niger in July, ascended the river Chaddon, and returned to England without the loss of a single man—all owing to the proper administration of quinine The party included sixty, and the expedition was in the river 180 days; twice as long as the expedition of '42, which, unprovided with quinine, ended in so fearful a loss of life. Surely no further evidence can be needed to prove that the daily and proper use of quinine in malarious regions is capable of so modifying the system as to render it capable of resisting the deleterious influences of climate, and of protecting individuals from intermittent or remittent fevers.

The dose usually prescribed under such circumstances is from three to five grains, regularly taken every morning before breakfast.—*Nashville Journal of Medicine and Surgery.*

MALPOSITION OF THE KIDNEYS.—The following case of Malposition of the Kidneys is related in the *N. Y. Medical Journal*, by Dr. Jones H. Butler. On the 14th of November last, the body of a negro was brought into the dissecting-room of the University of Maryland; during the dissecting, the abnormal position was observed as follows: "The kidneys, instead of occupying the lumbar region, were found in the pelvic cavity. Both organs were united or fused into one, with a central line or raphé making a longitudinal fissure over the surface of them, better marked on the posterior than on the unterior part. In length, they extended from the lower border of the lumbar aorta downwards, over the promontory of the sacrum, to the middle of that bone—in all, five inches; and in breadth measured three and three-fourths inches. The ureters sprang from the pelvis, which occupied the central anterior part of the organs, and then passed off on each side, and emptied into the bladder on each side. The tumor formed by the kidneys could be readily felt by examining with the finger *per rectum*. The arteries supplying the organs were four in number. Above, a single large trunk came from the aorta, just at the bifurcation, immediately in front of the sacra media artery, passed downwards, and before entering the substance of the organs, broke up into five smaller branches; on the left side, two arteries came from the left internal iliac, near its commencement, and on the right side an artery passed into the organs from the right internal iliac." The patient died of pneumonia.

RUBEOLA WITH PECULIAR FORM OF ERUPTION.—John H. Cobb, aged 13, (under the care of Owen Daly, M.D., of Hull General Infirmary), was attacked with rigors on November 24th, and admitted on the 27th in a severe febrile condition; having scattered irregularly over the extremities numerous spots, or rather circular patches, varying in diameter from one-quarter to three-quarters of an inch, of a dusky red color, slightly pale in the centre, not elevated, fading, but not entirely disappearing, on pressure. Similar, but larger, patches covered part of the hands, and enveloped the ends of the fingers. His face was flushed; lips dusky; tongue dry and glazed; pulse 120, very feeble; respiration hurried and abdominal, without cough or coryza. He was ordered milk-diet, beef-tea, six ounces of wine, and a saline mixture.

During the following week, fresh spots, exactly similar in character, appeared daily; and the hands and feet were quite enveloped by confluent patches; but on December 1st, the lower extremities were covered by a mottled rash like ordinary rubeola. This was more general on the following day; on the evening of which it began to fade, and rapidly disappeared. Desquamation of the cuticle followed, as extensive as in scarlet fever, the palms and palmar aspect of the fingers being quite denuded. His general condition steadily improved almost from the time of admission, and on December 20th he was discharged convalescent.—*British Med. Jour.*

TEACHERS' CONVENTION AND THE EXTENSION OF LECTURE TERMS.

THE circumstances attending the adoption of the resolution concerning the period of study, by the Convention of Medical Teachers, at Cincinnati, carry with them no small amount of significance. When the original proposition was put, that the term should not be less than three years, it failed to meet with general favor; and the unanimity with which the amendment of Prof. Gross, of Philadelphia, was passed, conclusively proved the importance which was attached to its further extension. The proposition coming, too, from a gentleman long engaged in public teaching, and associated with one of the first medical institutions in the country, is an earnest of the good faith and laudable desire of all those particularly interested in the advance of medical education. The origin of the motion, then, is unexceptionable; and the motives, it must be admitted, were as laudable as the necessities of the case are imperative. The probability, however, that it will be generally adopted is not so certain as we might expect. The main obstacle that we opine will be urged against it will be the conflicting interests of the several smaller schools. Many of these latter institutions, catering to the popular desire to manufacture doctors in a hurry, base not a small amount of their patronage upon the possibility of crowding very much learning into a small space of time; and while they make a show of many advantages, which are peculiar to themselves and the localities in which the institutions may be, give the students to understand that time is of the least importance. Such schools will doubtless strongly object to this movement, and will set up the cry that an unfair advantage is taken of their established rules, and that, consequently, no body of men have a right to dictate to them concerning a change so fundamental and so damaging to their patronage. But, after all, this resistance cannot but be short-lived, and those who are determined to hold out against the measure must inevitably, in the course of time, cease to exist. If, then, the resolution does no more than this—lessening the number of our small one-horse institutions—it will ultimately be the first step in the advancement of our college standard, and take the edge off the sneer with which our "manufactories of doctors," so called, are referred to by transatlantic medical men.

We have no doubt that the plan of extension will meet with the approval of the majority of students. It only is necessary to make a start with the coming fall to insure its success, and if but a few of the larger institutions would do this, they could sweep everything before them, and compel the smaller ones to follow their example. This is the only way a beginning can be made; the adoption of resolutions by a convention of never so respectable and honorable men, avails nothing, unless there is a proper spirit and determination behind to enforce them. The experiment can hardly be considered a dangerous one, as it is but a small increase of time compared with what the majority of our students are accustomed to spend in our colleges; the only essential change being the actual enforcement of such an attendance as to time, as shall be necessary to entitle them to final examination.

Another good effect of the adoption of compulsory measures in this respect, would be the prevention of the miserable system lately so much in vogue among many with the plea of limited time, of crowding two full courses into a year, by attendance during the summer months upon other institutions. While making this statement we are perfectly aware that it is the intention of these colleges to exact the legal requirement of three years' study in the office of a practitioner of medicine; but all who are even indirectly connected with these schools know full well that it is as easy to procure a certificate of the requisite amount of study as it is to get one of good moral character. This may be true of any college, or under any system of management; but we claim that it is more especially so in connection with the practice to which we allude.

As the question now stands, the length of time allotted to studies is all that can reasonably be asked for. It is now only enjoined upon the student to attend three full courses of lectures, and there is left to him a year to prepare himself for attendance at college. If, besides this, he be fortunate enough to reside in proximity to the school, he can spend not a little of his time in attendance upon such of the lectures as may agree with his preparatory studies.

The wording of the third resolution implies that it shall be obligatory on the part of the student to attend three full courses of lectures before he shall be entitled to receive his examination for a diploma. The difficulty in carrying out such a compulsory measure will be by no means great, and, practically speaking, there can hardly be any impediment at all to its general adoption for, as we have already intimated, there are not only a majority of the students who will attend in any event on lectures, but a great number consider it a privilege to remain connected with the college three terms in-

stead of two. All sensible candidates for a degree are well aware that their chances for success at the final examination are proportionately increased as they lengthen their term of stay beyond the time allotted; and to those who are in too great a hurry to do this, it does not, as far as any good to the profession is concerned, matter much whether they can graduate or not.

As regards the length of each course—that of five months—we are not much better off than we were before, save the naming of that period as the minimum. The larger colleges have almost to a single one adopted this as the standard, and, we are glad to say, by the establishment of summer courses, seem inclined to do more, so that there need not be on their part any change. But to those schools who have of late been curtailing their time and increasing their professors, the matter will be certainly somewhat different, and may seriously interfere with those pet little plans which they may have formed for making money easily, and having a decently large class of students. But we may say of these institutions as we have said of the students who attend them, that the profession can get along profitably without either. In fact, if the changes spoken of can fairly be inaugurated by responsible schools, so that the smaller ones are compelled to follow the example, one of two effects will follow: either very many of the smaller schools will be forced to raise their standard to the level of their leaders, or else pass out of existence altogether for the want of even a meagre patronage which may enable them to drag out a miserable and pitiable existence.

There is no question but that the medical mind is prepared for the extension of the term of study, and that the colleges that second the endeavor of the Convention of Medical Teachers will be appreciatingly rewarded by the patronage of the best class of young men, and the chances of a continued increase in attendance will be commensurably great in accordance with the spirit with which the intentions are carried out. As regards the increased expenses of board, etc., which such an attendance would involve, all we have to say is, that it would be too trivial to many to be weighed at all in the balance of expediency; and the number of those dissatisfied students who would complain of poverty would be very much decreased, when they discovered that they were compelled to spend the amount of time required, or else be deprived of a chance to obtain their examinations.

There does not seem to be much doubt but that the metropolitan schools will adopt the plan, their intention being foreshadowed in the inauguration of their summer courses; but as to the others, we must be patient and wait.

Thus far we are free from any of the epidemic influences of cholera. There have been but a very few sporadic cases reported up to the time of our going to press. The opinion of distinguished sanitarians is to the effect that the city and suburbs will in all probability escape the ravages of this dreadful scourge. But in view of this comfortable assurance of safety, it becomes a matter of no small concern to consider the probability of our being equally fortunate with reference to Yellow Fever. Everything, however, is being done by the authorities to prevent its entrance into our port, and we hope that their endeavors will be crowned with that success which they deserve.

We would especially commend the remarks made by our Philadelphia correspondent, in regard to the difficulties attendant upon reporting, to many of those gentlemen who are so willing to talk and so unwilling to have their remarks published. His views concerning the matter will certainly be endorsed by those of our readers who desire to be kept informed of the doings of our different scientific bodies.

Reviews.

On Railway and other injuries of the Nervous System. By John Eric Erichsen, Fellow of the Royal College of Surgeons, Prof. of Surgery and Clinical Surgery in University College, etc., etc. Philadelphia: H. C. Lee. 1867. 8vo. pp. 103.

The number of cases of railroad injuries that are constantly occurring, and the number of instances in which suits against railway companies are being multiplied, invest the particular subject treated of by Mr. Erichsen with a great deal of importance. The professional mind has of late, in regard to these cases, become tinctured with much of the prejudice that has belonged to juries, and physicians have persuaded themselves that many of the effects of shocks complained of by patients have no foundation in fact, and are only trumped up by the injured one for the sake of obtaining heavy damages. To such surgeons this little work particularly appeals. The subject of injuries to the nervous system, by comparatively trivial shocks, directly or indirectly inflicted upon the spinal column, is very lucidly discussed; and the reader, on perusing the work, will not fail to be convinced of the frequency, as well as danger, of these occurrences. The author assumes that a shock may be received by a mere concussion of the body as a whole, without giving any evidences of external injury, and ultimately lead to organic disease of the membranes or cord itself. The cases which the author cites in proof of this, and the deductions which he draws from them in regard to diagnosis and prognosis, are peculiarly valuable to the medical jurist. This particular part of the subject of railroad accidents has not been treated of in any work within our knowledge; and it is a fortunate thing for the profession that the distinguished London surgeon has added the weight of his name to the elucidation of such an important and interesting class of affections.

Chemistry of the Farm and Sea: with other Chemical Essays. By Jas. R. Nichols, M.D., Editor Boston Journal of Chemistry, Member of Mass. Institute of Technology, etc. Boston: A. Williams & Co. 1867. 12mo. pp. 122.

The work before us is calculated for the instruction of the public in matters of science, and will serve the purpose for which it was written. The author is well informed on all the subjects that he discusses, and has a faculty that will be appreciated by the general reader of making things clear and intelligible. It is a very

suggestive and edifying work to any who have not given attention to the applied sciences; but to the majority of our readers it would be simply as an old story told anew.

WHY NOT? A Book for every Woman. The Prize Essay to which the American Association awarded the Gold Medal for 1865. By HORATIO ROBINSON STORER, M.D., of Boston, Surgeon to Franciscan Hospital for Women, etc., etc. Boston: Lee & Shepard. 1867. 16mo. pp. 99.

THIS essay, we are glad to learn, has within the short space of a few months advanced to a second edition, giving unmistakable and gratifying evidence of its acceptance by the community.

TREATMENT OF PNEUMONIA with the Preparations of Veratrum. By DR. KOCHER, etc. (Behandlung der Croupösen Pneumonie mit Veratrum präparaten. Von Dr. Theodor Kocher, in Bern. Würzburg. Druck und Verlag der STAHEL-SCHEN, Buch und Kunsthandlung. 1866.)

DR. THEODOR KOCHER, of Bern, presents us with a work of ninety-four pages, on the "Treatment of Pneumonia by the Preparations of Veratrum." Considering the probability of the disease ending favorably in a certain time, if left to itself, Dr. K. thinks we should still seek for remedies which will *abort* it.

The book is mostly composed of the results, histories, and treatment of, and reflections on sixty cases of pneumonia, where veratrum was used, under the care of Professor Biermer, in Bern. The resina veratri viridis was given usually in $\frac{1}{8}$ grain doses, hourly, until four pills had been given; then stopped to avoid sickening. The pulse and temperature often fell very quickly. The mortality of these cases is stated at 8.3 per cent. The average duration of treatment five days and twenty-one hours. The veratrum is supposed to affect only the fever *directly;* it lowers the pulse and temperature. The crisis is only caused in the first twenty-four hours of the disease, near the time of the spontaneous cessation of the fever.

The indirect influence on the local process, rather than the avoidance of the consumption by the fever, causes the favorable statistics of the veratrum treatment. The remedy is contra-indicated where the fever is slight, or where the patient is so weak that he may not be further reduced. When not too much debilitated, and in drunkards, stimulants may be simultaneously employed. The necessary quantity of veratrum must be given in a short time, and the medicine stopped as soon as nausea or lowering of the pulse or temperature occurs.

THE CURABILITY OF PHTHISIS PULMONALIS. Examined Historically, Pathologically, and Therapeutically, etc. (Die Frage über die Heilbarkeit der Lungen Phthisen, Historisch, Pathologisch, und Therapeutisch, untersucht von DR. JOHN BAPT. ULLERSPERGES. Würzburg. Druck und Verlag der Stahel-schen Buch und Kunsthandlung. 1867.)

THIS is a book of 275 pages, on "The Curability of Pulmonary Phthisis." The disease is said to be the cause of about one-fifth of all deaths, and of about one-half of those occurring between the ages of fifteen and thirty years. The first part of the book is occupied with the relation of cases that have terminated in cure, under different methods of treatment.

The author seems to have drawn his material from various sources, French, German, English, and Russian authors being quoted. Indeed, Dr. U. speaks as if his work were intended as a resumé of all that has been written on the subject, with the addition of observations of his own.

The most important part of the treatment is considered to be prophylaxis. "It is easier to prevent phthisis than to cure the slightest case of it."

Among the prophylactic means is mentioned residence at the sea-shore. This is useful in chronic phlogosis of the pulmonary mucous membrane, with tubercle threatening or just deposited, but is injurious in the stage of softening.

Another important point in prophylaxis is the avoidance of marriages between relatives or tuberculous persons. The choice of climate for the residence of tuberculous patients has always been considered very important, and the advantages of the different places recommended are here very extensively discussed.

Among the methods of treatment proper, those by nebulized fluids, iodine, cod-liver oil, raw meat, and alcohol, etc., are mentioned at some length.

Reports of Societies.

N. Y. PATHOLOGICAL SOCIETY.

STATED MEETING, APRIL 24, 1867.

DR. H. B. SANDS, PRESIDENT, in the Chair.

OVARIOTOMY, EFFECT OF INTRA-ABDOMINAL LIGATURE.

DR. CUTTER presented the remains of the ovary of the patient upon whom he had operated a few weeks ago. The case was that of the old lady reported at the last meeting, who died the fourth day after the operation, from exhaustion. He desired simply to exhibit the specimen as an illustration of the effects of intra-abdominal ligature. There was found on post-mortem examination, union throughout the whole extent of the wound, and, with the exception of a little bloody serum in the cavity of the abdomen, nothing abnormal was noticed. The point at which the ligature was applied to the pedicle was considerably shrunken, so that the ligature itself, while being partially encysted, was quite loose; but what at first sight seemed remarkable, was that the vitality of the pedicle beyond the ligature was preserved. This he thought was in part due to a connecting band from the proximal side to the pelvis.

DR. SANDS thought that the latter circumstance could be explained by the recollection that a very large vessel was tied in a very thick pedicle, and that the subsequent shrinking of the tissues in the neighborhood allowed the artery to expand sufficiently to give the necessary supply of blood to the parts beyond. He also believed that the ligamentous band connecting the pedicle with the pelvis had considerable to do with the preservation of the life of the distal end of the ligated portion.

DR. POST presented a specimen of disease between the first and second phalanges of the finger of a child two years old. The disease existed about a year, and the finger at the affected point was so enormously swollen that the doctor was inclined to believe that the bone was affected. On removing the member by amputation, the said enlargement was found, much to his surprise, to be confined mostly to the soft tissues. The articulation itself was the seat of caries.

WELL DEVELOPED MAMMARY GLANDS IN A MALE.

DR. WATTS, Jr., exhibited an Irishman, fifty years of age, who was malformed in rather a remarkable manner. In the first place, he had a pair of well developed mammary glands, and secondly, his penis was only about three-quarters of an inch in length, and the different parts of the organ were proportioned in size. The subject of these phenomena was fifty years of age, was one of thirteen well formed children, had

been married, and was enabled to have sexual intercourse and seminal emissions. He never had any children. Since he has become a widower, he is not unfrequently troubled with libidinous dreams. There was no blood relationship between his father and mother. The mammæ had all the appearance and feel as if made up of lacteal tissue.

TUBERCULOUS DISEASE OF LIVER.

Dr. Lewis Smith exhibited a liver removed from a female seventy-six years old, who died of old age. In the left lobe of the organ was situated a circumscribed whitish granular cheesy tumor, having very much the appearance of a tuberculous mass. He was inclined to believe that the appearances were due to an hydatid cyst, which had undergone a distinctive metamorphosis. In confirmation of this view he quoted some remarks from Frerich's work on the liver. No microscopical examination sufficiently thorough had been made, for the purpose of finding the characteristic hooks of the echinococcus.

On motion, Dr. Smith was requested to make such an examination and report the result at the next meeting.

Dr. Smith next presented a lung taken from a child, who died at the nursery, Blackwell's Island. The patient was ten months old, and had symptoms of pneumonia twelve days preceding its death. The seat of the pneumonia was detected by auscultation and percussion; there was dulness on the right side and below the scapula, and some dulness, less in degree, on the left side. When this child had been sick about six days, it began to have a croupy cough. At the same time there was upon the left side considerable inflammation of the cervical glands and neighboring cellular tissue On examining the fauces there was noticed a considerable deposit of lymph upon the fauces, and a diagnosis of diphtheria supervening on pneumonia was made. The child finally died of debility. On post-mortem examination the faucial deposit was granular in appearance, and under the microscope revealed the fibrillæ, as well as the pyoid corpuscles. This deposit extended as far down as the rima glottidis. One point of interest was the impossibility of inflating that portion of the lung which had been the seat of pneumonia. He remarked that Bouchut had stated that in the first and second, and sometimes even in the third stage of that disease, the infantile lung was inflatable.

WAS IT A FRACTURE OF THE ACROMION?

Dr. Hamilton presented a scapula which had been sent him by a gentleman, asking if there had been a fracture of the acromion process. From an examination of the specimen he was enabled positively to decide that it was not. This conclusion was based, in the first place, upon the fact that the disjunction was in the situation of one of the epiphyses of the acromion. In passing, he remarked that the acromion process was formed of two epiphyses, the shorter one being very frequently found separated, and the other less often. It was this last one which, not being united, was mistaken for a fracture. In the second place, there was no displacement; and, thirdly, it had a perfect capsule. This last argument was used with the full knowledge that such a condition might exist after some fractures, but only in such as were kept constantly in motion. Lastly, at the seat of the separation there was an elevated crest or margin, acondition which was never met with in a case of fracture with a capsule. The patient was a male, seventy years of age, and a thorough examination of the skeleton failed to detect any other epiphyseal separations; an argument which, by-the-by, was used in support of the supposition that the lesion exhibited was a fracture.

EPITHELIOMA OF PREPUCE FOLLOWING CONGENITAL PHYMOSIS.

Dr. Hamilton next exhibited an epithelioma of the prepuce which he had removed a few days ago. The patient was thirty-one years of age, and had a congenital phymosis, and had never been able to retract the foreskin. About the latter part of last January he received an injury of the penis, in consequence of which it became swollen. About a month ago the integument in front of the extremity of the prepuce became thickened, and cracked. Instead of an ulceration at the latter point there was disclosed a fungus the size of a ten-cent piece, which was flattened, and had a firm and indurated base.

He stated that this was the seventh case of epithelioma of the penis upon which he had operated; and of these, five were examples of congenital phymosis. He regarded that simple circumstance in itself sufficient reason why we should make haste to operate upon all such cases in early life. He had observed that in all the cases it seemed to have commenced in the integument of the prepuce. In five of the seven it had already involved the gland; in all it seemed to have commenced in the prepuce. In six of the seven he had amputated more or less of the penis; in five of the seven had made amputations primarily, and in the remaining sixth the operation of cutting away the phymosis was extended to amputation on account of finding the penis diseased. In reference to the amputation he remarked that in all save the last he had used the knife and had been bothered with secondary hæmorrhage; in the last case, however, the écraseur was employed, and no such unpleasant results followed. From the satisfactory behavior of the stump in that instance he had made up his mind to prefer the écraseur hereafter.

Dr. Finnell presented a cæcum removed from a person who died of heart disease. The appendix vermiformis was found perforated with an alvine concretion, and adherent to the cæcum. No history of the case was obtainable.

Adjourned.

Stated Meeting, May 8, 1867.

Dr. Henry B. Sands, President, in the Chair.

INCISED WOUND THROUGH HEART.

Dr. Thomas C. Finnell presented, on behalf of Dr. John Beach, a heart taken from a man who was stabbed with a butcher-knife on the left side, below the nipple. The weapon entered the thorax, between the sixth and seventh ribs, pierced the pericardium and the left ventricle of the heart, cutting the apex across. He lived long enough to descend a flight of stairs, when he fell and expired. The lungs were much compressed with blood that filled the left pleural cavity.

DEATH PRODUCED FROM ABORTION.

Dr. Finnell presented another specimen, on behalf of Dr. Leo: the generative organs of a woman thirty-nine years of age. She was in the eighth month of her pregnancy, and tried to produce an abortion on herself by various means. She used a glass chimney as a speculum, before a mirror, and irritated the uterus with a whalebone, long hair-pins, etc. However, she did not succeed, and went to an abortionist in Amity street, who had performed a similar operation on her twice before. She was delivered of a child on April 4. Dr. F. saw her first on April 21, and diagnosticated

uterine phlebitis. Pulse was 130, and kept the same way for ten days. She died on the nineteenth day after the operation of pyæmia. She had marked chills twice a day a short time before her death, not much fever, but severe pain and vomiting.

Post-Mortem.—The uterus was much enlarged, and presented a dark appearance; the attachment of the placenta could be distinctly seen. On the left side of cervix uteri was an extravasation; abscesses were found in both ovaries, and matter exuded, on cutting into them. The veins were filled with coagula. The vagina had a small discoloration; the uterus was almost gangrenous, discharging a thick muco-purulent matter, of a yellowish color. There was no peritonitis, nor any other signs worthy of note.

ANEURISM OF THE RIGHT SUBCLAVIAN ARTERY.

Dr. Markoe presented the heart, aorta, and its principal branches, taken from the body of a man about fifty years old. The patient was a dry-goods clerk, married, and regular in habits, though not of robust health. About the 1st of January last he began to have occasional attacks of dyspnœa, for which he consulted Dr. Hunter, who recognized aneurism of the right subclavian artery, and sent him to the clinique of the College of Physicians and Surgeons. The aneurism was discovered about the size of half an egg, situated just where the artery emerges from the scaleni. The pulsation was very distinct and forcible, the tumor swelling out to twice its size at every pulsation of the heart. The pulsation of all the larger arteries of the neck was very active, though no other aneurismal dilatation was noticed. The same energetic pulsation was observed in the iliac and femoral arteries. The man's general appearance was pale and anæmic, though he suffered no pain, and indeed presented no symptom of disease except the occasional attack of dyspnœa, which most commonly came on at night. There was a marked bruit (de soufflet) along the course of the aorta, but no dulness in any part of the chest, which would indicate internal aneurism. The bruit was thought from its softness to be anæmic.

It was noticed that the pulse on the left side was very faint and small as compared with that of the right side. This paroxysm of dyspnœa increased gradually in frequency and in severity, and he finally succumbed on May 5.

The heart was enlarged, and its tissue had undergone some degree of fatty degeneration. The aortic valves were thickened, corrugated, and at their base calcified. The aorta was largely dilated, atheromatous and calcified. The innominata was natural in size, but somewhat irregular and puckered on its surface. The right carotid was thickened in its whole course, so that its calibre was diminished. The right subclavian was of natural size, till it emerged from the scaleni, and there presented a sudden dilatation, apparently of all the coats, which formed an aneurism, now much smaller than it appeared in life, entirely empty of blood, and occupying about an inch and a half of the vessel. Beyond this aneurism the artery suddenly resumed its healthy condition. The left carotid was slightly dilated, and the left subclavian, commencing beyond the thyroid axis, was so contracted that, at one point, its calibre was diminished at least two-thirds. All these dilatations were of the fusiform variety, and embraced all the coats of the artery. That the arterial coats were diseased was manifested not only from their thickened and irregular surfaces, but from the fact that the surrounding tissues were morbidly adherent to them at every point, making dissection difficult; a condition which would pretty certainly make a difference in the facility and success of any operation to be performed on them.

Dr. Markoe remarked that he had watched this case with unusual interest, as he had at one time hoped he might be able to do something for its relief by an operation. He did not believe that it was sound surgery ever to put a ligature on the subclavian in the first part of its course, as there was not room for a clot to form, on account of the return current through the vertebral, and in every case when death had occurred from hæmorrhage it had been from the distal side. He had determined in his own mind, if ever the opportunity offered, to apply in a similar case a ligature to the innominata near its bifurcation, and also one upon the common carotid, just above its origin. He believed that this was the only operation on subclavian aneurism which promised success. Dr. Mott, in his history of the operation on the innominata, makes the same suggestion.

GRANULAR DISEASE OF THE KIDNEY.

Dr. Noyes exhibited a kidney, which was brought to him by a country practitioner. The specimen was particularly presented to show that with the aid of the ophthalmoscope a correct diagnosis can be made of Bright's disease. He saw the patient in the latter part of January. The patient was a farmer, 49 years old; the last four months he had complained of impaired sight, loss of appetite, and an increasing weakness. Dr. N. found retinitis, an albuminous urine, and made a positive diagnosis of morbus Brightii. There was no heart disease.

Dr. Sands remarked, that he had examined a patient with albuminuria two months ago and also found no heart disease.

Dr. Noyes found in the case under consideration no ecchymosis in the retina, which is always seen in cases associated with heart disease.

ANEURISM OF CŒLIAC AXIS.

Dr. E. C. Seguin presented a specimen, which was removed from the body of a sailor, 36 years of age, who died on the 3d of May, in the New York Hospital. On admission, April 30, he gave the following history:

Two months previously he began to suffer from rheumatic pains in the legs, arms, and left side of body, which pains had been decidedly nocturnal. The pain in the abdomen he located in the epigastrium, going through to the lumbar region, around the left hypochondriac space; and he described it as very sharp and severe. He stated that until one month ago he never had any dyspnœa; that he never had suffered from acute rheumatism, or received any injury. Five years previously he contracted syphilis, and since has had skin and throat secondary symptoms. He had continued the duties of an able seaman during the first month of illness, but had after that time taken to his bed. He noticed about three weeks ago that lying on his back caused increased pain.

On being examined in the ward, he was found lying upon his right side, his knees drawn up, his face being pale and expressive of pain and anxiety. The tibiæ and ulnæ were found swollen and tender; and the glands about the elbows and neck enlarged. Great tenderness was found in the abdomen over the left hypochondriac region, the epigastrium, and over the lower ribs near the spine. In the epigastrium a pulsation was distinctly visible, and on applying the hand a little firmly, a distinct aneurismal thrill was perceived. Auscultation showed the heart and arch of aorta free from abnormal sounds, but about an inch above the

ensiform cartilage in the median line, a loud, hard systolic murmur was heard. On tracing it downwards, it appeared loudest at the apex of the sternal appendix, getting fainter below that point until lost midway between the umbilicus and pubes. In the back no true murmur was to be found, but a sort of shock or "thud," with the systole of the heart, was audible over the tenth dorsal vertebra. No aneurism was to be found in any of the superficial arteries. A careful examination of the urine failed to reveal albumen or casts.

The diagnosis was made of aneurism of the aorta in the neighborhood of the cœliac axis.

Preparations were made to put him upon the postural plan of treatment, and meanwhile morphia was given hypodermically to allay the pain. Unfortunately the issue was nearer than anticipated; on May 3, at 1 P.M., the patient put his hand upon the tumor and fell into a fatal syncope. No imprudent movement was made previous to this.

The autopsy was made 24 hours post-mortem. The abdominal cavity contained an enormous quantity of blood; 3¼ lbs. of clot, and 4 lbs. of liquid blood. The heart and lungs were healthy. The aorta was removed as far as its division in the pelvis. The valves were healthy, but the vessel was extensively atheromatous; in the arch anteriorly an aneurismal pouch had commenced to form. Lower down opposite the cœliac axis, no dilatation was to be found; the branches of the vessel arising in a normal manner. But on tracing out these branches, a large aneurism was found connected with the cœliac axis proper, adherent on the left to the supra-renal capsule, on the right to the lobus Spigelii of the liver, and above intimately connected with the diaphragm. The branches of the axis escaped from the lower part of the sac, whose walls, ¼ of an inch thick, were rough internally, made up of very old layers of fibrin; the rupture having taken place (an opening ¼ inch across) at the anterior edge of the adhesion with the liver. The sac contained but a little liquid blood and clot. The remaining abdominal vessels were healthy.

The spleen, liver, and kidneys were healthy. The physical signs in the case are remarkable, and might have been sufficient for the making of an exact diagnosis. There was no doubt as to the weight of the aneurism, and dilatation of the aorta might have been excluded on account of the absence of bruit in the back. It is very remarkable that the patient had never suffered from vomiting or any disorder of the digestive organs excepting constipation.

The Society then went into executive session.

EXTRAORDINARY OBESITY.—A woman named Hogan, wife of a comfortable farmer living at Kilmastulla, Ireland, died recently from obesity. Mrs. Hogan, in her youth, showed symptoms of attaining more than ordinary proportions, and she continued to increase in size until, at the time of her death, she had reached the extraordinary weight of forty-eight stone (672 pounds)! She was, for the last few years of her life, scarcely able to walk, and for some time past entirely confined to her bed.

HOOPING-COUGH.—A correspondent of the *Lancet* says that he has very often succeeded in cutting short the paroxysms in this disease by applying a blister or sinapism to the nape of the neck or the shoulders of the little sufferer. This may be repeated as occasion may require. It has, of course, no effect upon the bronchitic and pneumonic complications.

Correspondence.

THE PUBLICATION OF REPORTS OF SOCIETIES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—With the advent of warm weather in earnest, many of our patients are departing for the sea-side, the springs, the mountains—anywhere out of the heat, and out of the bustle of the city; and some of the unfortunate can't-get-away doctors are parting for a time with their domestic endearments to lead a bachelor life in the city, until the season becomes suitable for the return of their families. Summer courses of medical instruction are suspended, clinics closed, societies adjourned; what matters of professional interest are there to write about? In the want of something to chronicle, let me chat to you a bit about *the publication of Reports of Societies in medical journals.* This is a subject which during the past year has exercised some of the members of the profession here a good deal, and culminated at a business meeting of the County Medical Society, a few months ago, in a resolution prohibiting the report of their discussions in medical journals, whether by professional reporter or member of the society, without certain official sanction, and the individual supervision of those members participating in the discussion. So, sir, unless your correspondent has influence enough in the fall, to have this resolution, or motion, or whatever it was, reconsidered, you will have to strike from your columns the reports of the Philadelphia County Medical Society.

Now, sir, what are the objections urged against the publication of the reports? That they are not official, that they are often incorrect, or to use an offensive phrase, "garbled," and that they are not subjected to the revision of the speakers.

Now, sir, in my opinion, the report of a discussion, such as has been contributed at times to your columns, is not intended as an official transaction, nor as a substitute for such; it is simply a record of such comment as certain subjects call forth at the time. Every one who reads the Journal knows exactly the manner in which discussions on special medical subjects take place, and does not expect the language or precision of an official promulgation. He knows that a paper is read by a member, or a subject introduced extemporaneously; that comment is elicited from those who listen; that pertinent matter overlooked by previous speakers is referred to by succeeding ones; that peculiar views are enunciated, and those already advanced endorsed or combated; that sometimes speakers arise, occupy a good deal of time without bringing forward any new idea, or merely reiterate what has already been brought forward more distinctly; that others branch off from the subject and give valuable dissertations on extraneous topics; that later in the discussion some one reviews the entire debate; and finally, when all that have desired to express their views remain silent, the discussion closes.

There is a good deal of information to be gained from these discussions; practical experience is narrated which would never be otherwise recorded; the accordance or non-accordance of theories subjected to the practical test—and naturally a medical journal is anxious to avail itself of whatever value arises therefrom; and hence the prominent place usually accorded to Reports of Societies in such journals.

To print in full a paper which may have taken an hour or more to read, to print in extenso the remarks

that it may have called forth, is the province of those having in charge the publication of the official Transactions of the Association.

The province of the Medical Journal is to mention the subject, present a short synopsis of the paper, or describe its tenor, indicate the nature of the discussion which ensued, and call attention to anything new or valuable that may have been elicited in consequence. This is to be done to the best of the ability of the party to whom the matter may be intrusted by his editor, and a certain amount of discretionary responsibility must rest upon that individual, as to how much, and what much of the paper and discussion is to be reported. A full report is always too bulky for the pages of a medical journal, and would often, perhaps, command perusal less frequently than a synopsis; and then many societies claim equal representation.

To present for individual revision the copy of the remarks made by those taking part in the discussion is irksome, for many reasons. Not so much on account of a change of language which some might desire to substitute, but because of the impossibility of pleasing every individual as to the particular report of his own remarks. One gentleman would re-write the whole thing, inserting many things which escaped his attention during his own participation in the debate, and perhaps nullifying entirely the value of the remarks of some later speaker, who had been induced to take part solely because such topics had not been alluded to before. Another gentleman would send his copy back re-written, occupying three or four times the space that had been allowed for him, with a polite note, that he would prefer his remarks to be published as re-written by himself. Another gentleman would keep his copy three, four, or twelve weeks after all the rest had been returned, and thus publication would be delayed, the editor annoyed, and the reporter worried. Then, after all was ready for the press, some matter would have to be cut out, and how to do this without offending those who had gone to the trouble of correcting the copy of their own remarks, would puzzle even those most easily offended.

Where a Society publish their Transactions regularly, in pamphlet, or in some certain medical journal, all these matters are attended to, and there is a completeness about the production that would be sought for in vain in a journal account. In the latter, elegance of diction is not often looked for, because but few possess such extemporaneous ability; methodical consideration of the subject is expected only from the party introducing it, because it has been his duty to prepare himself; those following, often speak on the spur of the moment, and their remarks lack the finish that would pervade an essay emanating from their study; so that it is necessarily inferior in every respect to an official record. Yet for that reason it need not be incorrect, because it records something a gentleman did say, but did not mean to say; nor need it be garbled because it has selected from a gentleman's remarks those considered most novel or most instructive, or changed the record into narrative, in order to economize space.

Besides, the record of a Society meeting, as usually reported, without referring the copy to the speakers for revision or approval, may prompt participants in a discussion to more care in their remarks, to a habit of coming to the meeting booked up on the subject, so as to avoid the possibility of saying what they did not mean to say. But, where a good deal of latitude is to be allowed in re-arranging remarks, interpolating what was forgotten, etc., less attention will be paid to the subject at the time of speaking by those who would depend upon a future opportunity to correct inadvertencies or supply deficiencies; and thus the discussion would not then be faithfully reported.

I trust that those who have virtually secured for the present the exclusion of reports of the Philadelphia County Medical Society from the pages of the medical press, will be led to adopt views more consonant with the liberal catholicism of the profession, that their colleagues elsewhere may not be deprived of the chance of occasional participation in the crumbs of information which are sometimes dropped from the deliberative table of that body.

Messrs. Lindsay & Blakiston, medical publishers, of this city, have moved their salesroom from the ground floor of their establishment to the second story, which has been neatly fitted up for the purpose; and it is said to be their intention to devote themselves to the publication of works on medical subjects more exclusively than heretofore. Their recent editions of Aitken's Practice, of Waring's Therapeutics, and of Cazeau's Midwifery, have been introduced into the U. S. Army. They announce the reception of the third part of Trousseau's Clinique Médicale, and the appearance of a new edition of Harris's Dental Dictionary; of Taft's Operative Dental Surgery; and of their Physicians' Visiting List for the coming year.

Yours truly,

C. J.

Philadelphia, July 6.

NEW METHOD OF "COMPLETING"

THE REDUCTION OF OLD DISLOCATIONS OF THE SHOULDER.

TWO CASES REPORTED.

By DR. M. C. CUYKENDALL, of Bucyrus, Ohio,

IN A LETTER TO DR. HAMILTON.

To the Editor of the Medical Record.

Dear Sir:—The manœuvre adopted by Dr. Cuykendall, in his last attempt, was original and ingenious, and is, I think, worthy of a notice in the Record.

Yours truly, F. H. Hamilton.

The following is the report of the case:

Prof. Hamilton, 64 Madison ave.—*Dear Sir*—Believing that cases like the following interest you, I beg leave to report it. I would have done so at the time I treated the case, but I saw a notice that you were about publishing the third edition of "Fractures and Dislocations," and I deferred it. Since I procured that work, and perused it in part, I have concluded to send you the report, which is as follows:

Mr. V. Seaton, of this county, aged 62 years, a farmer, of spare habit, fell from his horse, and dislocated the right shoulder, forwards, under the clavicle.

An Irregular, who saw him a few minutes after the accident, pronounced it a sprain, and advised cooling lotions. Seven weeks afterwards, he applied to me, when the head could be distinctly felt, and seen, in the sub-clavicular fossa.

I made three attempts, of one hour each, at reduction, with Jarvis's Adjuster, assisted by Drs. Meyer and Keller, of this place, and failed, as I believe, because we only made extension downwards, and the axilla pad, from its shape, pressed too hard upon the edges of the pectoralis and latissimus dorsi muscles, although we filled the axilla as well as we could. The patient was fully under chloric ether each time, and before applying the adjuster, the arm was forcibly rotated, and moved in different directions some fifteen or twenty minutes. There was an interval of twenty-four hours between each trial, and, after the third time, the parts

became so sore and painful, that the patient decided that he would have nothing further done. However, twelve days after, it being sixty-four days after the dislocation, he consented to another trial, and this time, assisted by Dr. Richey, of this county, I succeeded.

The patient was laid upon the floor, the double pulley secured to the wrist, and Skey's knob in the axilla, and put fully under the influence of chloric ether, and extension applied directly downwards, breaking up many adhesions, but not reducing the bone. I then secured the opposite arm, and made extension at right angles for some time, but, not succeeding, I secured the scapula with a band across the top, and made extension directly upwards, breaking up many and extensive adhesions, and, as I thought then, placing the head of the bone in its socket; but, upon removing the pulleys and bringing the arm down the head was found resting upon the edge of the glenoid cavity, and no extension, that I afterwards applied in any direction, did any apparent good. I, as a last resort, secured the pulleys above the elbow, the knob in axilla, flexed the arm, and made extension downwards and forwards, and when well extended I moved his body under the pulley ropes, so as to bring the arm forcibly across the breast, and then keeping up the extension, I had Dr. Richey place his knee upon the top of the scapula, and lock his fingers around the elbow, while I placed my knee against the elbow and locked my fingers around the top of the scapula, and directing the extension removed, we forced the bone upwards and outwards to its socket. During this last operation, the breaking of adhesions was perceptible, not only to Dr. Richey and myself, but also to the patient, who was then partially recovered from the effects of the anæsthetic. We had the patient under the influence of chloric ether four hours. His recovery was rapid, and he has perfect use of his arm.

This is the second case of *old* dislocation of the humerus, where I have succeeded in *completing* the reduction by securing the scapula and *pushing* the bone upwards and outwards, after having failed with *pulling*.

Should your time permit you to do so, I would be pleased to receive an acknowledgment of this, with your views.

I am, sir, very respectfully,

M. C. Cuykendall.

THE EFFECTS OF IMMERSION OF LUNGS IN ALCHOHOL IN RELATION TO THE QUESTION OF INFANTICIDE.

To the Editor of the Medical Record.

Sir—On the 19th ult. I was called to inspect three infants that had been found in a street ash barrel. Suspicion of infanticide being entertained, an autopsy was ordered by the coroner, the results of which I think are worthy of record. The bodies had the appearance of fœtuses of five, six, and seven months' growth, respectively. They had apparently been preserved in alcohol. The cords in each had been properly cut and secured. There were no unusual marks on the surface, and the presumption was strong from external examination that the bodies were those of fœtuses that had been kept in alcohol for exhibition.

The internal organs were somewhat hardened by the preservative fluid in which the bodies had been placed. The lungs had the appearance peculiar to fœtal life. Their condensed structure, small size and sharp edges of their lobes proved to my mind that they had not been ed.

Both lungs, with entire thoracic contents, were thrown into water and *floated buoyantly*. Large and small sections of lung acted in the same way. The small pieces were firmly pressed and still floated. A very small piece when squeezed with a great deal of strength was made to sink. The compression required to produce this result was far more than is necessary to expel air in ordinary cases when gas is generated from putridity.

The peculiar character of these lungs I think must be due to the effect of the alcohol upon them. Pieces of *liver* thrown into water floated just as the lungs did. The appearance of the organs was not such as is usually seen when decomposition has set in. There were no air vesicles on the surface, nor change in their internal structure nor fetid ordor. It is possible that the alcohol merely modified the putrefactive process, causing a very different change in the tissue from that produced by exposure to the air or water.

The lungs of the three bodies were subjected to the same tests with like result.

This peculiarity of tissues subjected to the action of alcohol, it appears to me, has an important bearing on medical jurisprudence. A case might occur where the body of an infant, in suspected infanticide, should be preserved in alcohol for a length of time before being subjected to post-mortem examination and the hydrostatic test make it appear that a still-born child had been born alive. It is true that we are advised before the application of this test to press the lungs thoroughly, but to expel the air the amount of pressure required in the lung subjected to the action of alcohol bears no proportion to that ordinarily used to free it from the gases of putrefaction.

Wooster Beach, Jr., M.D.

EXTENSIVE ADHESION OF PELVIC ORGANS, ETC.,

AND THE ACCOMPANYING SYMPTOMS.

To the Editor of the Medical Record.

Sir—I beg leave to offer the following account of the singular developments of a post-mortem examination recently made. The subject of this examination was a married lady, twenty-six years of age, without children. About a week prior to her marriage, in November, 1865, while residing in Chicago, Ill., she took cold during her monthly period, by sleeping in a damp room, which caused a suppression of the menses, followed in a few days by "inflammation of the womb." She was very dangerously ill, and her life was at one time despaired of. The ordinary symptoms of this acute disease gradually assumed a chronic form, and others of great severity and intractable nature were superadded. Thus she continued to suffer throughout the winter from an exhausting diarrhœa, from frequent and painful micturition, and from daily paroxysms of agonizing pain in her back and hips. By spring she was reduced to the condition of a skeleton, having lost 50 lbs. of flesh. Her weight in the fall had been 128 lbs.—it was now 76. Very naturally, she was thought to be "in a decline," and her disease was pronounced incurable by her attending physicians; their diagnosis being, "consumption of the bowels." It was not even thought safe to arrest the diarrhœa, "lest it should lead to a deposit of tubercle in the lungs." There also had existed for several years a grave disease of the *heart*, which, however, had not given rise to any urgent or painful symptoms. In this condition she was brought from Chicago in a "sick car," and reached her home in Suffield, Conn., April 12, 1866. A month

later she came under the care of the writer, having previously abandoned all hope of recovery, and having become quite averse to any further treatment.

From a careful survey of the case it was thought that her disease was *not* tuberculous nor constitutional, but *local*, and confined mainly to the pelvic organs. Upon examination the os and cervix uteri and posterior wall of bladder were found exceedingly sensitive and irritable, and patient could not bear the slightest pressure externally in the pubic region. As a state of chronic inflammation, with great irritability of these organs, is not uncommon in women, producing a train of distressing symptoms not unlike those of our patient (with the exception of the diarrhœa, which soon yielded to treatment), her case was not considered hopeless. Without going into details it is sufficient to state that by a dogged perseverance on the part of her very wilful doctor and most tenderly sympathizing mother, and with a patience *more than soldierly, because womanly*, on *her* part, in the use of fomentations, poultices, neuralgic liniments, plasters, &c., in the hypogastric and sacral regions, together with injections and suppositories per vaginam and per rectum, and various internal remedies (her extreme emaciation and debility forbidding the use of more efficient treatment by leeches, cups, and caustics), she was at length brought to a condition of comparative ease and comfort—suffering only from her evacuations, which at times were still very distressing. The persistence and occasional severity of these troubles sometimes shook my faith in my diagnosis, but never suggested any such extensive organic lesions as the sequel will show were found after death. The neuralgic pain in her back and limbs wholly subsided. She became very cheerful and hopeful, and by the 1st of August had gained 20 lbs. of flesh. She was at this time able to ride out, and some weeks later made a four days' visit to her sister, in Meriden, 40 miles distant: going and coming by stage and railway. Her monthly periods were never established, except by the occurrence of vicarious menstruation in the form of epistaxis, with generally an aggravation of all existing symptoms. Though subject to such ailments, she continued to improve till about the 1st of January, when, happening to take cold after a fatiguing day's labor (upon a *hoop skirt!*), she had an attack of acute rheumatism, which confined her to the bed three weeks or more. From this attack she never fully recovered, lost her appetite, never after sat at the table with the family as before. She remained in a state which made it doubtful whether she could rally or sink for some weeks, and died quite suddenly April 4.

In accordance with the patient's often expressed wishes an examination of the body was made ten hours after death, with the assistance of my professional brethren, Drs. A. Rising and W. H. Mather.

The heart was found much enlarged—of more than twice its normal size—weighing a pound and a quarter. The hypertrophy of the left ventricle was especially noticeable, its walls being fully an inch in thickness. This condition was found to have been occasioned by an ossific deposit in the mitral valve, causing something of a contraction in the auriculo-ventricular orifice, but more of an insufficiency in the valve itself, with consequent regurgitation. The stage of dilatation apparently had not been reached, hypertrophy much predominating, which would account for the extraordinary vigor of the patient's circulation. Her extremities were never cold, notwithstanding her low condition, and she required much less clothing on her bed than any other member of the family. This disease of the heart, no doubt, originated in former attacks of rheumatism, to which the patient had been subject. Further investigation led us to believe that it was not the principal cause of her ill-health nor of her death, although it was of long standing. Previous to her illness her husband could see a book shake in her hands across the room, from the violent action of her heart, and could always feel its impulse through her hand resting on his arm; and yet, strange to say, no complaint was ever made by the patient in regard to her heart while under my care.

The liver was of large size, its left lobe extending quite across the epigastrium into the left hypochondrium, where the spleen was found firmly adherent to it throughout three-fourths of its extent. As the liver had contracted no other adhesion, and was healthy in appearance, it was inferred that the patient had suffered an attack of splenitis in former years; but no such attack was ever recognised. She often complained of a feeling of tightness across the epigastrium, especially after eating. Beyond this slight inconvenience it is believed no harm resulted from this unwonted intimacy between two not very neighborly organs.

Directing our attention to another region of the abdomen, we quickly discovered evidence of most extensive disease in the adhesion to the bladder and uterus of all the adjacent viscera. Indeed, it is no exaggeration to say that there was an agglutination of all the pelvic organs! In endeavoring to separate coils of intestine from the bladder, its posterior wall was easily torn off; showing that the inflammation of the organ had been so intense as to produce an organic degeneration of portions of its sub-mucous cellular tissue and muscular fibre. The mucous membrane was of a pale ash-color, with a patch in the bas-fond of a dark slate-color. The capacity of the organ was reduced to a few ounces, and its contractibility must have been greatly impaired. All of which is in harmony with the pain and difficulty attending its evacuation, and with the small quantity of water voided, but not at all in harmony with its healthy appearance, since no unusual color or odor, nor any muco-purulent, or other abnormal deposit (with the single exception of the urate or lithate of ammonia, which is sufficiently common in those subject to rheumatism), was ever noticed.

Of the uterus and its ligaments only a cursory examination, I regret to say, was made, and nothing remarked beyond their adhesions.

The small intestines showed unmistakable signs of having been involved in the inflammation of the neighboring organs, and from their adhesion to them could have had but little peristaltic action; which fully accounts for the patient's diarrhœa in the earlier months of her sickness, and for her subsequent impaired digestion and painful defecation—the latter, however, may have been occasioned by a fissure in ano, or internal piles; but no examination was made of the rectum, and only the extremely contracted state of the large bowel noticed, which seems to be commonly observed in autopsies.

The lungs, kidneys, and other organs not mentioned, were healthy, and no tubercles were found in any part of the body.

Yours truly,
J. K. Mason, A.M., M.D.

Suffield, Conn.

THE DEATH OF DR. GEO. K. AMERMAN,

OF CHICAGO.

To the Editor of the Medical Record.

Sir—Death has once more visited our profession, and claimed his tithes of the choicest and the best. Dr. George K. Amerman expired at his home in Marcellus, N. Y., on the 20th June, 1867, cut off in the prime of life by that fell destroyer, *phthisis pulmonalis*. For nearly two years his health has been failing, but with

indomitable energy the doctor continued to hold his clinics at the hospital during the winter, and to visit his patients, in spite of the admonition of his friends, until he was completely prostrated by tubercular pleuritis and laryngitis. Rallying a little, he left the city, early in April last, fully determined to visit Europe during the summer, and confident of complete recovery. It was only after an interview with the highest medical authority in New York, that he could be persuaded of his danger. Returning then to the home of his boyhood, he arrived in time to close the eyes of his wife, who died, after a short illness, of acute *pneumonia*. His disease seemed to receive new impetus from this shock; he sank rapidly, and ceased to breathe at 4.30 A.M., June 20th. This sorrowful event was announced to the Chicago Medical Society at their last meeting. The following Resolutions were presented by a committee for the action of the Society:

Having been informed of the death of their associate, George K. Amerman, M.D., the members of the Chicago Medical Society desire to testify for the deceased their respect and their feelings of personal loss, by these resolutions:

First, That in this affliction we lament the death of one who, long identified with our community, though young in years, was old in professional renown. A man whose life was a career of brilliant success, a Christian in deed as well as in name, at the height of his reputation,—he has now received the crown of immortality.

Second, That to the members of our profession we earnestly commend the example afforded by the life of our departed associate.

Third, That to the surviving relatives of our beloved friend we tender this expression of our sympathy, in view of their bereavement, ever desiring with them to bow in humble acknowledgment of the almighty power of that God in whose hand are the issues of life and death.

Fourth, That a copy of these resolutions be furnished to the relatives of the deceased, and to the medical journals and daily newspapers of the city.

The report of the Committee was accepted. Dr. Ross then read a technical history of the last illness of the departed brother. Dr. A. R. Gore, who had known Dr. Amerman from infancy, being invited to address the Society, proceeded to relate the following interesting facts concerning his friend:

At the time of his death Dr. Amerman was in his thirty-fifth year. The son of a rural farmer in Central New York, his boyhood was distinguished by fondness for study, and by disinclination to the drudgery of farm work. He was obedient and kind, but *good for nothing* on the farm. He early manifested a passion for teaching, and at the age of sixteen his only ambition was to become a school-teacher. His father, however, proposed that he should study medicine. To this he consented. Placed under the guidance of Dr. Gore, then a practising physician in Owasco, New York, he pledged himself to pursue the study of medicine, subject to the direction of his preceptor, for five years, before attempting to commence its practice. He accordingly attended three courses of lectures in the University Medical College of New York, graduating with honor in the spring of 1854. Still acting under the guidance of his preceptor, he secured a position for one year on the resident medical staff of Bellevue Hospital. The next year he became a member of the resident surgical staff of the same hospital. There, in the enjoyment of the friendship and confidence of the most distinguished physicians and surgeons of New York city, Dr. Amerman completed the fifth year of his course of study. At once received into partnership by his former preceptor, and removing to Chicago, he commenced the practice of his profession in 1856. He was appointed surgeon to the Illinois Central Railway, an office which he filled with great credit until the time of his death. He was also one of the surgeons to the City Hospital until that institution was closed, during the war; and was the leading spirit in the surgical staff of the County Hospital from the time of its renovation until failing health compelled him to surrender his large and lucrative practice.

After listening to the remarks of different gentlemen who united in eulogizing the memory of the deceased, the resolutions were adopted, and the Society adjourned.

A series of similar resolutions was adopted by the Medical Board of the County Hospital, an institution of which Dr. Amerman may be said to have been the founder and chief executive officer. Beloved by all his associates, he possessed the unbounded confidence of a large circle of patients; and throughout the whole range of an extensive acquaintance, his influence was felt to a degree which no other physician in this city could approach.

CHICAGO, July, 1867.

New Instruments.

A POST-MORTEM NEEDLE.

BY J. H. HOBART BURGE, M.D.,

BROOKLYN, N. Y.

THERE is no part of an autopsy so much dreaded as the *sewing up*. Hardly a surgeon has escaped pricking himself with the needle. Sometimes the integument is so tough that we are in danger of puncturing our fingers with the blunt extremity of the needle. A thimble does not obviate the difficulty, since with its best aid the needle may either turn back or break. At my last experience of this sort, I resolved to devise an instrument which should answer all the indications. The following is the result:

The needle may be of any convenient length, with the eye sufficiently removed from the end to admit of its being accurately fitted to the calibre of a cylindrical stile, which has a firm handle at the other extremity. I hardly need describe its use. When threaded, pass it through the integument like an awl,—seize the needle with the thumb and forefinger, and withdraw the handle,—now draw the thread tight. Re-insert the needle in the handle, and take the next stitch, and so on, and *sew* on. It is hoped this little contribution may not only prove a comfort, by facilitating that which is sometimes a real labor, but also by saving much valuable time to those who procure for us our most valuable pathological specimens, and better still, that it lessens the number of those sad sacrifices to science—the deaths from dissection wounds. The instrument is made by George Tiemann & Co., 63 Chatham st., New York.

NOVEL METHOD OF MANUFACTURING GAS.—According to a Swiss journal, a means has been discovered of utilizing cockchafers. The *Estafette* of Lausanne states that between four and five millions of these insects were recently sent to Friburg for the manufacture of gas, and the residue forms an excellent carriage grease.

New Publications.

THE ESSENTIALS OF THE PRINCIPLES AND PRACTICE OF MEDICINE. A HANDY-BOOK FOR STUDENTS AND PRACTITIONERS. By HENRY HARTSHORNE, M.D., Professor of Hygiene in the University of Penn. Auxiliary Faculty of Medicine, etc., etc. Philadelphia: H. C. Lea. 1867.

ON LIGATURE OF FUNIS. By A. F. A. KING, M.D. Washington, D. C.

Medical Items and News.

PERSONAL.

DR. ERNST KRACKOWIZER has been elected one of the attending surgeons to the New York Hospital, *vice* Dr. Willard Parker, resigned.

DR. THOMAS M. MARKOE has been appointed a Visiting Surgeon to Bellevue Hospital, to fill a vacancy occasioned by the death of Dr. William H. Church.

DR. WILLIAM H. VAN BUREN was recently elected one of the Consulting Surgeons to the New York Hospital.

DR. JOHN SIMMONS, for a number of years Medical Adviser to the City Prison, died of congestion of the brain, June 14th, ult.

MR. HOFF AND THE N. Y. ACADEMY OF MEDICINE.—At the last meeting of the Academy of Medicine, the following resolutions were unanimously adopted:

Whereas, W. L. Hoff, proprietor or agent of the "Hoff Malt Extract," is issuing publications through the secular papers, and by means of pamphlets and circulars, professing to quote favorable opinions expressed in a report of a committee of the Academy;

And, *whereas*, the said Hoff is widely circulating a letter purporting to have been written by a Fellow of the Academy;

And, *whereas*, the publications of said Hoff are so adroitly and designedly worded as to impress the mind of the reader with the belief that the Academy has endorsed his nostrum, and has thus apparently compromised its dignity and professional standing—Therefore,

Resolved, That the N. Y. Academy of Medicine does hereby proclaim and declare that it has not expressed any opinion in regard to "Hoff's Malt Extract," and that any and every use of its name in recommending said Extract is unauthorized by the Academy.

Resolved, That a copy of the above preamble and resolutions be sent to the Medical journals of this city, and that the Medical journals throughout the country be requested to copy the same, in justice to the Academy and the profession.

QUARANTINE INTELLIGENCE.—From all the West Indian Islands reports have recently been received that yellow fever is prevailing to an alarming extent. On the 8th of last month the United States Consul at Kingston, Jamaica, notified the Collector of Customs at this port that yellow fever was prevailing at that place in the form of an epidemic of a malignant type, and that at least twenty-five per cent. of the cases had proved fatal. From New Orleans many contradictory reports have been received, and one of the latest telegrams relative to the sanitary condition of that city was received by Messrs. H. B. Cromwell & Co., on the 3d inst. It contains the following: "Am officially advised by the Board of Health in this city that only eight cases of yellow fever have occurred during the last two weeks; six proved fatal; no indications of its assuming an epidemic form. City generally healthy; one hundred and seven deaths during the week ending Sunday."

At Quarantine there has only been one death during the present year, and that occurred some months ago. At the present time there are no cases of contagious sickness on board the hospital ship, all reports to the contrary notwithstanding. On the 4th inst., the bark King Harold, from Matanzas for Greenock, Scotland, put into this port in distress. She reported that the captain died in hospital of yellow fever before leaving Matanzas. The mate then assumed command, and during the voyage he also sickened and died of the same disease, and on the 1st inst. two of the crew died. On arriving at this port the remaining members of the crew were completely prostrated with over exertion and fear, and it was found necessary to remove several of them to the hospital ship Falcon, where they are now recuperating.

The steamship Rising Star, from New Orleans, is now detained in the lower bay for the purpose of fumigation. —*N. Y. Herald, July 7th.*

AN ORGANIZATION OF MEDICAL TEACHERS for the purpose of advancing the interests of medical education has been formed in England.

THE CATTLE PLAGUE has reappeared in several parts of Great Britain.

THE LEAVENWORTH MEDICAL HERALD.—We have received the first number of this Medical Monthly, and are well pleased with its contents and style of make-up. It is under the editorial management of C. A. Logan, M.D. and T. Sinks, M.D., both of whom give evidences for their fitness to the undertaking. We wish success to the enterprise.

THE AMERICAN JOURNAL OF DENTAL SCIENCE has been revived; Drs. A. Snowden Piggot and F. J. S. Gorgas are the editors. It is published at Baltimore.

ABORTION IN COWS.—The New York Legislature at its last session made provision for a commission to investigate the subject of Abortion in Cows. Prof. John C. Dalton has been appointed one of the commissioners, and will be assisted in his investigations by Drs. Carmalt and Haigh of this city.

MEDICAL SOCIETY OF NEW JERSEY.—The Medical Society of New Jersey held its one hundred and first session in Newark, on the 28th and 29th of May. The following officers were elected for the ensuing year: President, John C. Johnson, of Blairstown; Vice-Presidents, Thos. J. Corson, of Trenton, Wm. Pearson, of Orange, and Thos. F. Cullen, of Camden; Corresponding Secretary, C. Hodge, of Trenton; Recording Secretary, Wm. Pearson, Jr., of Orange.

SPECIAL DEPARTMENTS for Eye, Ear, and Skin, have been established at the London Hospital.

ALBANY MEDICAL COLLEGE.—The following appointments have recently been made in the faculty of this institution. Dr. S. Oakley Vanderpoel, M.D., Prof. of General Pathology and Clinical Medicine; James E. Pomfret, M.D., Prof. of Physiology; and John V. Lansing, M.D., Prof. of Materia Medica.

PREPARING OXYGEN.—Sub-chloride of copper when exposed to the air absorbs a large quantity of oxygen, and when the metal is afterwards gently heated, readily parts with the gas.

MEDICAL BARONETCIES.—Mr. Wm. Lawrence, the eminent surgeon, has recently had the honor of a baronetcy conferred upon him, and Dr. G. Duncan Gibb, of Westminster Hospital, has succeeded to the baronetcy of Gibb of Falkland, Fife. We regret to learn that the former gentleman has since been stricken with palsy, and that but faint hopes for recovery are indulged in.

HYRTL'S MAGNIFICENT ANATOMICAL MUSEUM has been purchased by an American College for $8,000, it having been offered for sale at the Paris Exposition. Hyrtl is the Professor of Anatomy at Vienna, and from personal observation, we are prepared to testify to its value. What college has the treasure?

CHOLERA AT VIENNA.—On May 4, a man was attacked with cholera at Vienna, the first case of the season.

ELECTRO-THERAPEUTICS.—Two wards have been set apart in the Vienna Hospital for Electro-Therapeutical purposes.

PROFESSOR JUNGKEN, of Berlin, at seventy-six years of age, is still in active practice, performing such operations as extraction of cataract, iridectomy, and enucleation of the globe.

TO BECOME WELL-INFORMED PRACTITIONERS. — You must mingle with other men in medical societies, otherwise you will soon become contracted in your views; for, you must remember, if you are guided simply by your own limited experience, you will surely go wrong. Laws and deductions in medical sciences ought to be drawn from large numbers of observations. Let your libraries be in receipt of the really valuable medical literature, as it comes from the press, especially of the monographs and works of the most distinguished authors. Let your books be your greatest luxuries—let your shelves be the last places where you economize in your expenditures. Money spent there is well spent; new books are as necessary to you as tools are to a mechanic; you cannot do your work well without them. Do not confine your purchases to home publications, but keep your orders at the importer. Let your office table be supplied with the most prominent domestic and foreign journals and reviews. As Tyler Smith has expressed it—"In consultations two or three meet; in societies hundreds stand face to face, and have the privilege of exchanging thoughts, but in the periodical press we have the collision of thousands of minds busied with the same subject; thus more truth is elicited, more progress made than could be by solitary thinkers."—*Address of Prof. F. Donaldson, University of Maryland,* 1867.

ABORTION AND INSANITY.—I have for many years received and treated patients whose insanity was directly traceable to this crime, through its moral and physical effects. Some have, after recovery, given a sad chapter of perverted life, and disclosed the revolting fact that the suggesters, aiders and abettors of this heinous offence against God and nature—this rude violation of the best instincts of women—were persons of their own sex. One woman told me, and the statement was verified by her husband, that seven successful abortions were procured on her by one of her female friends—and both these women were highly respectable persons and members of the church. When, in broken health and after failure in the *eighth* attempt, she applied to a physician, he informed her of the criminality of the act, its dire consequences to health, and advised her against the continuance of such a practice. She subsequently, however, obtained the services of a charlatan, who succeeded in inducing abortion; and, some months later, this woman was admitted to the Asylum in wretched health and suffering from melancholia, which her pastor, ignorant of her true history, attributed to religious excitement. A minister recently informed me that, in his congregation, in a country village, one of the prominent women approached his wife with a proposition that she should destroy her prospective offspring, declaring that she thought it right to do so, and mentioned others who resorted to the practice, rather than be troubled with children. It cannot be possible that such women are ignorant of the crime of infanticide. The only plea that can be made for them is that they do not comprehend the turpitude and criminality of the act, and do not recognise the solemnity of marriage and the true dignity of maternity. One could almost wish that such women might not be mothers.—*John P. Gray, M. D., 24th Annual Report of State Lunatic Asylum for* 1766.

THE ANATOMY OF THE GORILLA.—The variation in the size of the brain is considerable in the human species, but I think the position and the quality of the brain have more to do with the intellectual manifestation in man than the size, although the intelligence is visibly altered according to the weight of the cerebral deposit. The cranial capacity of a young gorilla about a year or two old is from twenty to twenty-two cubic inches. Supposing a subsequent development equal to that in man, this would produce an animal of a high grade of intelligence, but it is only the bones of the skull that increase in the gorilla, as it grows in years, not the brain itself, which remains about the same in the adult specimen as in the infant young. This proves conclusively that the animal has very small power of intelligence, and from my own experience I believe the limit of that intelligence is reached within a year or two after the birth of the young gorilla. In the Caucasian skull the average capacity of the brain is about ninety cubic inches, and the maximum has been found to be one hundred and fourteen inches. In man the position of the head and the curvature of the vertebra column make the erect position the only natural one any other being quite painful after a while. This difference is an organic one, resulting not from habit, but from natural structure. The whole frame of man proclaims that he was made to carry himself in an erect posture; and, unlike the quadrumanous apes, his superior extremities do not perform any service in the act of locomotion. Then comes the head, too, with its enormous expansion of brain; the condyles of the occiput are brought forward to the base of the skull, and by this balance of the head on the neck bone, the arms in man are in more symmetrical proportion with the length of the legs. The lower limbs, or legs, are longer than in any apes, the pelvis is broader than it is long, the iliac bones inclined steeply, the humerus is larger than the fore-arm, and, finally, the thumb of man is much larger than in any ape, and the most useful member of the hand. According to Dr. Gratiolet, of Paris, even in the lowest idiots the brain presents the material and zoological character of man, and, although often inferior in appearance to that of the chimpanzee or other apes, it is nevertheless an undeniable human brain. Disease or degradation in continued reproduction may dwarf a man, but will never make him an ape. Although there is great dissimilarity between the long frame of man and that of the gorilla, there is also an awful likeness, which in the latter resembles a hideous caricature of a human being.—*M. Paul du Chaillu.*

RIGID PERINEUM; DIVISION OF THE SOFT PARTS.—Dr. Beattie, in the *Dublin Journal of Medical Sciences*, recommends in cases of rigid perineum, that the soft parts be divided by probe-pointed scissors sufficiently to allow the head of the child to pass. By this method of procedure, the duration of labor may be shortened sometimes by several hours.—*Cincinnati Journal of Medicine.*

HEPATIC ABSCESS: TWO CASES.

By R. B. MAURY, M.D.

PORT GIBSON, MISS.

In the midst of conflicting opinions concerning the etiology of this disease, it is just to suppose that the publication of all fathfully recorded cases, which may throw any light upon the subject, will be acceptable to the profession.

There is a very large mass of clinical evidence which associates this lesion with the ulceration of dysentery; and though a number of excellent observers seem inclined to believe that this relation is not that of an effect to a cause, but that the two diseases are the joint effect of a common cause, I do not think they have adduced satisfactory reasons to support such a view; still less do I think that facts will sustain them in endeavoring to ascribe hepatic abscess to remittent fever; or that in dysentery there is necessarily or generally (outside of India) any special derangement of the functions of the liver.

With these views the history of two cases is here presented: 1. The first is that of George H., an old negro, between 65 and 70 years of age, who came under my care early in February, 1860, for the relief of chronic dysentery and enlarged prostate. The enlargement of the prostate had been a source of trouble to him for nearly three years, and became rapidly more so after I saw him. He had suffered from dysentery about fifteen months. He died 28th of June, 1860. Nothing of peculiar interest had been presented in the history of the case, further than the disease of the prostate, and for the examination of this an autopsy was held ten hours after death.

The usual appearances of senile hypertrophy of the gland were presented. The third lobe was enlarged, and had proved a serious obstacle to the passage of urine: the bladder was thickened and ulcerated. The kidneys presented no appearance of disease. The large intestine was studded with ulcers, chiefly along the course of the descending colon and rectum. The liver, to outward appearance, was healthy, but upon being opened, was found to contain two abscesses in its right lobe; these were small, and were circumscribed by a distinct sac; they were of an oval shape, and respectively about one and two inches in long diameter; they seemed to be quiescent or retrograding, no inflammation being apparent in their walls; one contained pure pus somewhat thickened; the other contained a yellowish matter of cheesy consistence, which was evidently pus also. The lungs were healthy, with the exception of old pleuritic adhesions.

During the time that this man was my patient, no sypmtoms were presented which attracted attention to the liver in any way, and I was surprised to find the abscesses after death. He had had no attack of fever for several years, and his case may fairly be quoted as an illustration of that relation which has been found to exist between hepatic abscess and dysentery.

In connection with this case I may add, that two years before, I saw in Bellevue Hospital, a similar instance in which multiple circumscribed abscesses of the right lobe were stumbled upon in a *post-mortem* examination of a case of chronic dysentery.

2. My second case was that of H. S., a young man, 32 years of age, a native of Switzerland, who presented himself on 7th June, 1866. He was of splendid physique, and had been keeping bar for twelve months, but his proper occupation was that of a stone-cutter, which calling he had followed up to the date of his becoming a soldier in the army of Northern Virginia, five years before. During his term of military service he had never been wounded, and with the exception of two slight attacks of diarrhœa, which had lasted a few days only, he had been entirely exempt from disease. In his whole life he had but one attack of illness; in this all the symptoms pointed to the liver, and for it he was, for several months, under the treatment of a physician in Memphis; this occurred eight years before. For ten years his habits had been very irregular, and occasionally he drank to great excess; now and then, of late years, after unusual indulgence in drink, he would suffer from "little bilious attacks" for a day or two. He had never had syphilis, had never been jaundiced, nor had he ever had hæmorrhoids.

Three months previously to his consulting me, immediately after a debauch, and while suffering from a severe cold and cough, he was suddenly seized with violent pain through the region of the liver from side to side: this continued for several hours, when the pain disappeared from the left side; but became fixed on the right, and extended thence to the abdomen. His physician thought the disease bilious colic, and gave mercurials for several days, but without much relief. He soon came under the care of another physician, who considered the case one of pulmonary disease. Under his treatment the febrile symptoms passed away, and the patient convalesced so as to return to business and old habits.

When I saw him in June, his appearance was nearly that of health, and he complained of nothing except a dull pain at base of the right chest posteriorly and laterally. He had no cough, the bowels and kidneys were acting properly, and the skin was moist; but the pulse was 110. On physical examination, there was found slight comparative dulness at the right base posteriorly; over the same region vocal resonance was somewhat diminished, respiration feeble, and the heart sounds abnormally distinct: with these exceptions, no deviation from health was found on a very careful examination of both heart and lungs. I was embarrassed in diagnosis, and was inclined to think he had had in February an attack of pleurisy with effusion, which had not been entirely removed, and that he now had a subacute attack. He had never had epistaxis, nor had he ever vomited blood. Iodide potass. internally, tr. iodine to the chest externally, were prescribed.

On the 14th June he returned, being worse: pain was on the increase, bowels confined and urine highly colored: skin very moist: pulse 110. He was advised to take one grain of calomel morning, noon, and night, for two days, and then to have it gently carried off by small doses of sulphate of magnesia. From this time to the 20th of June, he was observed to have fever every evening and night, followed next morning by heavy sweats; the pain steadily increased, and now required the use of morphine in small quantities; the appetite failed, and the tongue became red and divested of epithelium at the tip.

On the 20th June a decided tumor, five inches in diameter, was made out on the right side of the body, about the base of the chest, and corresponding to the hepatic region; its lower margin was on a line with the tenth rib; it presented no redness, but its temperature was raised above that of the surrounding tissue; the right rectus abdominis muscle was very hard and resisting; anterior posterior vertical hepatic dulness was somewhat increased; there was no pain referred to the right shoulder. The bowels were moved naturally every day or two; there was no nausea; the urine, though free, was high colored; sp. gr. 1024; no albumen,

no biliary coloring matter, and no biliary acids present in it. In the forenoon, the pulse was 100; the temperature in the axilla 98° to 99°; in the afternoon, pulse 115 to 120, and the temperature 101°.

Poultices to the tumor, and morphia at night, constituted the treatment at this time. The case now presented the appearance of hepatic disease, but all the recognised causes of abscess of the liver could be excluded. The patient had never had remittent fever, nor dysentery; nor had he ever had any symptoms of biliary calculi.

On the 5th July, my notes state that the patient was evidently losing ground; that he had become pale, anæmic, and sallow; much emaciated and very feeble; the hectic symptoms were decided and regular; the tumor had enlarged and become very painful, so that opiates were required constantly. Elixir vitriol was given to control the heavy and exhausting sweats. The temperature in the axilla, in the foornoon, did not rise above 98°; in the evening it was 101°.

July 7.—Under the influence of chloroform, the tumor was explored, and punctured with a tenotomy knife; a very small opening was made and pus evacuated in moderate quantity, with great relief to the patient's sufferings. The pus was healthy in appearance, and of no peculiar smell. He was ordered to use stimulants freely, and concentrated nourishment.

July 14.—He loses an immense quantity of pus, which is of a reddish-brown color; is failing rapidly, the pulse becoming more frequent, and the urine very scant; will take nothing but stimulants, and food in very small quantity; sweats all the time profusely.

July 25.—A large slough is forming around the opening made for the evacuation of pus; frequent small hæmorrhages have occurred and coagula often obstruct the orifice; the tongue is naked, dry, ulcerated, and the same condition seems to have extended to the pharynx; deglutition is almost impossible. The pus now shows signs of decomposition; the urine looks like strong ley, but no bile can be detected in it on careful testing. Pain is complained of in the left hypochondrium, when he turns on that side to have the abscess dressed. To this time the tension and resistance of the rectus and other muscles on the right side of the abdomen have been well marked: no pain has been referred to the right shoulder.

July 30.—He died this day. Autopsy held one hour and a half after death; body warm; no rigor mortis; emaciation excessive.

The body being opened, the lungs were found very pale, and presented, anteriorly, large patches of dark pigment; they were both adherent over a very great extent of the costal pleural surfaces: the adhesions were firm and old. With this exception there was no evidence of disease about them. The pericardium contained about an ounce of serum; the heart was so completely covered with a superficial layer of fat, that the muscular tissue could be discerned in two or three places only; otherwise it was healthy.

The cavity of the abdomen being opened, the liver *in situ* did not appear enlarged; its color was a yellowish-brown, and it presented to the naked eye the appearance of fatty degeneration. Slight and easily torn adhesions connected the upper surface of the left lobe with the diaphragm; the under surface of the same lobe was adherent to the anterior wall of the stomach, and when separated from it, showed that an abscess had pointed there, and would in time have emptied itself into the cavity of that viscus. The outer portion of the upper surface of the right lobe was also adherent to the diaphragm, and at a point corresponding to the external opening through which pus had been discharged during life, the adhesions were very thick and strong, and further examination showed that here a large abscess in the right lobe had pointed and emptied itself. On the upper surface of the right lobe, near the median line, was seen the thinned wall of a third abscess, which must soon have contracted adhesions with the diaphram, and would ultimately have emptied itself into the right pleural sac. The wall of this abscess was here not more than two lines thick, very convex, and the pus coud be seen through it before it was opened. The intestines *in situ* appeared normal; there was no peritonitis, except at the points where the adhesions mentioned had been formed.

On removing the liver, it was found thickened on its posterior margin, being nearly double the normal thickness; and upon dissection there were seen in the right lobe two large abscesses, already described, each the size of a child's fist, and with jagged irregular walls, no sac circumscribing them. The abscess in the left lobe was nearly as large as either of those in the right, and was of the same character. The contained pus was of a greenish yellowish color, and unlike that discharged during life. The abscesses were each distinct, and had no connexion the one with the others.

Besides these, there was found, near the outer margin of the left lobe, and on its under surface, a puckered cicatrix, the remains, without doubt, of an old abscess of small size, which was tied to the transverse colon by a fibrous band an inch long; the band was of a whitish color, and very hard, and so was the cicatrix, and neither presented any traces of recent inflammation. This feature is of especial interest in connexion with the attack of the liver from which the patient had suffered eight years before. A minute inquiry into the history of that attack, however, failed to establish the existence at that time of any of the known causes of abscess. The portal vein appeared healthy. The gall-bladder filled with yellow inspissated bile contained no calculi, and presented no appearance of ulceration. The stomach and several feet of small intestine were carefully scrutinized with a view to discover traces of old ulceration, if any existed, but nothing was found: the entire length of the small and large intestines was free from disease.

The kidneys presented no appearance of change, except that they looked fatty like the liver; their capsule was easily separated, and nowhere adherent. Suprarenal capsules were normal. Pancreas was so likewise. The spleen was a little larger than usual, but appeared healthy. No enlargement of mesenteric glands.

It is to be regretted that, in the study of this case, no clue could be found to the cause of the abscesses; the same may be said of the case presented by Dr. Geo. Pepper to the Philadelphia Pathological Society, February 14, 1866. The puckered cicatrix found in the left lobe, and bound by a fibrous band to the transverse colon, without doubt the remains of an old abscess, was probably a connecting link between his last illness and the attack from which he suffered eight years before. It is possible that he then had multiple abscesses which became encysted and remained stationary; that, in one of them, the pus underwent those degenerative changes necessary to absorption, the cavity of the abscess was obliterated, and only a cicatrix left to mark its place; the other three, after being inactive for a period of eight years, for some unknown cause took on new inflammation, and proceeded to the destruction of life.

That such a course is pathologically possible, may not be easily demonstrated, but it may be inferred from the remarks of Mr. Paget on old abscesses.

"The abscess has a natural tendency to open, unless all the inflammation in which it had its origin subsides. Inflammation appears to be not only conducive, but es-

sential to the spontaneous opening of abscesses; for where it is absent the matter of chronic abscesses will remain like the contents of any cyst, quiet for weeks, or months, or years." (*Surgical Pathology*, 3d American edition, p. 283.)

Special attention was paid to the temperature throughout the case, and the thermometer was never found to vary from the result given in the foregoing history.

SPHYGMOMETRY.

By E. SEGUIN, M.D.,
NEW YORK.

The pulse, as the external expression of circulation, has always been the beacon of physicians; and though pathological temperature, as expressed by the thermometer, bids fair to take the lead in diagnosis, the *pulse* may finally remain what it primarily was, if we improve the means of perceiving and reading it, as we have the other clinical signs.

The appreciation of the pulse is not necessarily confined to the medical touch. In a time not very far back, physicians had only the bulb of their fingers to perceive it. Then the detached second-hand of the watch came to their aid; and lastly, we have the "pulse writer," the sphygmograph, to add precision to perception, and at the same time register accurately the variations of pulse curves.

A revolution of this sort is neither to be deprecated nor avoided; it is merely to be complied with, or submitted to, not in a spirit of blind restlessness and of worshipping of what is new, for novelty sake; but with the steady and holy spirit of progress; not as the *absolute* best, but as the *present* best instrument of observation of the phenomena of circulation.

The instrument of Professor Marey serves to perceive circulatory phenomena unknown, or imperfectly known, and to record them.

Though the pulse may be considered as a *unit*, it may also be—it has been in fact—studied analytically in regard to its volume, strength, rhythm, frequency, and the shape of its waves. The three first properties may be perceived by the medical touch; the fourth may be guessed by the same sense, but can only be measured with a chronometer; the *shape of the waves of the blood* escapes almost entirely the most gifted fingers, and what is known as the "dicrotic pulse," stands as a monument of the incapacity of our unaided sense to perceive anything further.

We admitted that the volume, strength, and rhythm may be perceived by the touch; but is it sure that they uniformly and always are? If so, how is it that physicians appreciate them so differently, and express them so variously, that they hardly understand and trust each other about the pulse? Medical tact has never been especially educated in schools or hospitals, and physicians have had to form their own notions about it; and no particular language could possibly connect their essentially individual ideas on the subject. This judgment is, perhaps, more forcibly expressed in the language of two men of great authority. Prof. A. Flint, Jr., says: "It is evident that few of the characters of a pulsation, occupying as it does but a seventieth part of a minute, can be ascertained by the sense of touch alone." —(*Physiology of Man*, vol. i. p. 251.) And "considerable practice scarcely teaches us to estimate the exact degree of the alterations of the pulse; but certainly not with sufficient distinctness to convey to others an accurate idea, or even to be able ourselves to compare one observation with another." (Dacosta in *Diagnosis*.)

This double incapacity to read the pulse with the tact even aided by the watch, and to express it in words susceptible of being agreed and assented to, has led ingenious minds to contrive instruments susceptible of completing the observations begun with tactile imperfection. Before speaking of the last and best of them, we ought not, in justice, to omit the first one. As far back as 1833, Dr. Jules Herrisson presented to the Institute of France his *Sphygmometre*, accompanied with an excellent notice, and sixty observations of diseases of the heart, observed with his instrument. The sphygmometre had for its object to *render every action of the arteries apparent to the eye*. Its first advantage, expressly says the author, is to enable the physician to *write down* an exact description of the pulse during health, and to keep it at the standard to which he ought to bring the pulse back in case of disease.

It was to be applied in hospitals, to allow the pupils to judge with their own eyes, instead of relying on the assertion of the teacher, whose experienced touch would not give the same sensation as their inexperienced one. In consultation every physician might apply the instrument in his turn and exhibit it to all. In written consultations a far greater degree of accuracy was promised by measuring the movements of the pulse, than by describing them in words. Changes might be written down as often as they occurred, according to the march of the disease, or to the effects of remedies. The sphygmometer gave indications of some disease of the chest that percussion or stethoscopy could not find. It revealed certain particularities of the arterial circulation which the tact could not detect.

Its construction—the device of a reputed engineer, Paul Garnier—was very simple, and rather in keeping with the few rude medical and surgical instruments of that time. It consisted of a glass tube backed by a paper with the graduated figures marked on it. The end of this glass tube was inserted into a steel stem, terminated by an inverted cup, which was closed by a piece of gold-beater's skin stretched over its mouth, and secured by a rim, as is the head of a drum. The reservoir was filled with mercury, and communication might be intercepted between the cup and the capillary glass-tube by a stop-cock. When the heart or pulse were to be examined, the sphygmometre was secured *in situ*, its ups and downs noted, and the stop-cock applied whenever any point reached by the mercury needed to be ascertained.

It was a measurer, not a writer of the pulse; it actually showed it, what the sphymograph does not do —but somebody had to write its results, otherwise they would pass away unrecorded

Imperfect as the sphygmometre may have been, but pregnant with the future progress of diagnosis, it was presented to the appreciation of the Institute of France, where it received an official, that is, deadly reception from the commissaries. Magendie killed it, under the *pretence* that there was a discrepancy between the results of the two observers requested by the commission to experiment upon the same patient with the new instrument; but in reality for the *reason* that the eminent reporter was, or expected soon to be, engaged himself in experiments of the same nature. This plain accusation, of which we are not judge, but often proffered in similar cases, is from Dr. E. S. Blundell, who, in 1835, published the sphygmometre in London, with some modifications of his own, but giving full credit to Dr. J. Herrisson for his discovery. But it takes men like Fulton, and discoveries like his, to resuscitate from the scientific guillotine of the Mazarine palace. Herrisson's and Blundell's ideas on sphygmometry were sunk in oblivion. Vierordt took up the French idea—as it is usual for Germans to do—and transformed the sphygmo-*meter* into a sphygmo-*graph*. Progress, in one

sense, since the German instrument recorded the pulse; retrograde, in another sense, since it gave only the ups and downs of the waves, but not their peculiar undulations, which could be plainly read on the sphygmometer. Vierordt's instrument, however, did not attract the notice of the profession.

To Professor Marey, of the *Collège de France*, belongs the honor of having taken up the idea of Herrisson, giving it a new form, with the aid of recent mechanical ingenuity, and to have presented it at a time when the foremost men of the profession seemed ready to forward it, together with other improvements in diagnosis. The sphygmograph partly belongs to Herrisson for the idea, partly to Vierordt for the mechanism, but is evidently Marey's instrument. Of it exclusively we shall speak hereafter.

It does not give positively the volume, nor the strength, nor the rhythm, nor the frequency, though it indicates more or less these properties; but it does give positively the shape of the waves assumed by the circulating fluid; shape that the tact alone cannot perceive with any degree of precision, nor the language retrace from the tactile impression in words readily understood.

It serves already to register the undulations of the pulse dependent upon: First, organic changes in the channels of circulation; Second, functional alterations of the same, in disease; at various stages of disease; and during the morning and evening oscillations of fever.

But the chief use of the sphygmograph will be, as admirably foretold by Dr. Herrisson, to determine the normal pulse in health as a standard of comparison for future clinical observations; to determine it in infancy, in youth, at the climacteric epochs of life, and in any critical circumstance which may modify it. For, let us remember, the movement of the circulation is not invariably identical in all men, at all ages, nor in the same man under various contingencies. Whilst physiological temperature, once established for our race, holds good as the standard of health for everybody, physiological circulation presents such changes above and below its mean reckoning that, when we are called to a new patient, we never know, and can rarely suspect, what—if any—was the deviation of the healthy pulse from the would-be average. In this trying and frequent occurrence, we know very well what the pathological pulse is; but how can we form a judgment upon the distance which separates this pulse from the healthy one? since to establish our proportion we miss the most important term, the normal pulse.

In this respect alone the sphymograph will fill up a larger gap in our means of diagnosis. The thing is simple enough. Nearly every profession but ours has its landmarks. The police, for instance, has its *passports*, wherein the features, proportions, and individualities are recorded, so that a thief, wherever he goes, may be attended to according to his desert. But, strange enough, wherever an honest man falls a prey to accidents carrying with them disorders of the vital forces, even incapacity of communicating *de voce* with a physician, no record of his normal pulse, general habits, etc., can be found in his pocket; he has no *passport* throwing light upon his past health and reflecting that light upon the course to be pursued in his treatment. Thus men have been bled to death, because the power of their pulse was unknown to their attending physician; and others have ruptured important vessels in the act of vomiting, which would never have been provoked by an emetic, if certain curves in the waves of their pulse had previously revealed the state of these vessels. What signify eighty beats in a patient, whose normal pulse is seventy, and in another whose normal pulse is one hundred, if both standards are ignored by the physician? And what meaning must be attached to the absence of every fifth or seventh beat if it has lasted for years, or just made its appearance? The which we do not know. Nothing but records of the sphygmograph can give us any clew as to the physiological pulse, the basis of all pathological judgment. Here, more than anywhere else in diagnosis, conjecture must make room for positive knowledge.

But the sphygmograph has met with two objections, which happily bear not upon its principle, and hardly upon any temporary defects in its construction.

1st. "The very *perfection* and *nicety* of the instrument," says A. Flint, Jr., in his admirable treatise on Physiology of Man, "presents almost insurmountable difficulties in the way of its use by the general practitioner." Though this objection bears more upon our personal incapacity than upon the instrument, we hope to see this last improved, so that its handling will become more easy to practitioners. Anyhow, the difficulty resulting from the want of skill of physicians in using delicate instruments of precision, needs to be removed; the sooner the better. Nowadays surgeons handle efficiently instruments that Ambrois Paré would not have known how to use; ordinary mechanics and single girls easily manage instruments of labor that their grandparents would have been burned for as the devices of witchcraft; and we (average physicians) are accused by a competent writer, and likely not without reason, of being incapable of handling the most efficient instrument of diagnosis, *because* of its *nicety* and *perfection!* This avowal cannot put to shame the instrument, but those who cannot manage it. And this incapacity leads us to remark, that in our medical colleges and hospitals there is nothing like a systematic training of the *medical senses*, very little of handling of the instruments of physical diagnosis, and none at all of the manœuvring of the instruments of positivism in diagnosis, as the sphygmograph. Can it be hoped that this deficiency, once signalized, will be soon supplied?

2d. The other objection to the sphygmograph comes from its writing the pulse on a straight plan, so short that it can only receive the imprint of the moves taking place during ten seconds. But as there are changes of rhythm which are separated by more than that time, such changes may not chance to be included in our observation, or may be reproduced very irregularly on these ten-second diagrams. But this imperfection could easily be corrected by adapting to the sphygmograph of Marey a circular plan like Hierordt's, but moving in an ascending spirole, which would present to the pen a field sufficient to write down the undulations of one or two minutes.

We did not hear of any other criticism of the instrument of Professor Marey, and therefore we deem it as valuable to the practitioner as it has been to the physiologist—foremost among our means of positive diagnosis.

Festival Dinner to Drs. Wade, Staats, and McNaughton.—The Albany Medical Society recently gave a festival dinner in celebration of the completion of half a century in the practice of medicine by Drs. James Wade, Barent P. Staats, and James McNaughton. The affair was as interesting as it was unique. Speeches appropriate to the occasion were made by Drs. Staats, McNaughton, Alden March, and others. The recipients of the honor are still, we are happy to say, in the enjoyment of good health, and "may," in the language of one of the toasts, "their days be filled with the abundance and beauty of a glorious autumn, and their lengthening years be crowned with honor."

OVARIOTOMY—REMOVAL OF A MALIGNANT TUMOR—RECOVERY.

By EDW. T. CASWELL, M.D.,

OF PROVIDENCE.

The operation for ovariotomy has become so well known, and so many cases have ended successfully, that an apology might be needed for the publication of the present case, were it not for the character of the tumor. It occurred in the practice of Dr. Miller, and is reported with his consent.

M. M., an Irish woman, 45 years of age, married ten years ago; her husband died two years since. She has had two children and two miscarriages; the last child was born six years ago, and the last miscarriage occurred in the same year. Ever since the death of her husband there has been an irregularity in menstruation. She first noticed a swelling in the hypogastric region a year ago last August, and another prominence showed itself last March in the left lumbar region. The swelling constantly increased—the lower becoming the most prominent. There was some tenderness and pain. She first came under Dr. Miller's eye about midsummer. The abdomen was then much distended with fluid, and in the latter part of August she was tapped, and five quarts of a clear fluid were withdrawn. The distension, however, was not wholly removed. In the course of a month she again suffered from the amount of fluid collected, and upon examination it was decided that there was a tumor of ovarian origin, and the operation of ovariotomy was proposed, to which the patient readily yielded her assent. The operation was performed on the 10th of October. At that time the abdomen was as much enlarged as it is in the seventh month of pregnancy. Fluctuation was very manifest over the left side and towards the middle line. There were two comparatively hard prominences to be felt through the abdominal walls corresponding to the two points at which the patient had first noticed the swelling. The one in the left lumbar region seemed the most firm, and was somewhat sensitive upon pressure. There was some doubt expressed as to the result of the operation, but in accordance with the earnest entreaties of the patient it was determined to proceed with it.

The patient was placed upon a table in a warm room and brought under the influence of chloroform. After she was completely unconscious, ether was substituted for the chloroform. An incision was made in the middle line, commencing nearly an inch below the umbilicus, and carried down almost to the symphisis pubis. On reaching the peritoneal cavity there was a gush of fluid, proceeding from a small cyst, which was found to be attached to the anterior wall of the abdomen. The surface of the tumor was now exposed. It was lobulated, and in some of the lobes there were cysts manifestly containing fluid. There were some points of adhesion to the walls of the abdomen, and some to the intestines. These adhesions were broken up without much difficulty —one of some size attached to the small intestines was separated with the écraseur. The ones containing fluid were then punctured. From one a quantity of clear serous fluid escaped, from another a gelatinous substance, and from another a thick whitish fluid, resembling rice-water in appearance and consistency. Another portion of the tumor was decidedly hard. It was manifest therefore that the tumor was not as simple as had been supposed. It proceeded from the left ovary. The pedicle could be distinctly felt, and the whole of the tumor surrounded. In order to gain more room the original incision was extended up to the umbilicus. The tumor was now everted. The pedicle was attached to the broad ligament, and just outside of it could be seen the mouth of the Fallopian tube, with a small cyst as large as a pen upon its extremity. The pedicle of the tumor was isolated, and three ligatures of double-twisted saddler's silk, waxed, were passed through it, thus dividing the pedicle into three portions. Each was tied securely, and one end of each ligature was cut off close to the pedicle; the pedicle was then cut off without hæmorrhage. The small cyst upon the extremity of the Fallopian was then cut off, and as a slight flow of blood followed the knife, a single ligature was passed around the bleeding extremity. The pedicle was then returned into the abdominal cavity, and some fluid, which had unavoidably escaped into the cavity of the pelvis, was absorbed by soft sponges. During the latter part of the operation sickness at the stomach occurred, and caused some embarrassment, in consequence of the movement of the bowels which it created. They were, however, retained in their place as far as possible by gentle and firm pressure upon warm cloths. The edges of the wound were then brought together and fastened by six sutures of silver which passed through the peritoneal coat. The intervening spaces were drawn together with adhesive plaster, and the ligatures brought out at the lower extremity of the incision. A thick woollen pad was then laid upon the abdomen, and over this a broad swathe. The patient was then put to bed, and came out from the effects of the anæsthetics without unpleasant symptoms, save a quite feeble pulse. She received some stimulus immediately after the operation, and after a short time, as she complained of pain, a small anodyne.

The tumor weighed six pounds and a half. It was a composite tumor, made up, as has been said, of cysts and intermediate portions of considerable firmness; the same variety of contents was observed in the cysts as has been mentioned. The hard portion of the tumor, when examined microscopically, showed numerous round proliferous cells with nuclei and nucleoli, and presented the general appearance of medullary cancer. The whole tumor corresponded very well to the description which Rokitansky gives of cystoid tumors combined with medullary carcinoma. The result of the examination, therefore, seemed to lead to an unfavorable prognosis eventually, even if the patient should recover from the operation.

The patient was allowed a mild diet, with occasional doses of an anodyne for the first few days. Each night, for a week or ten days, she received a subcutaneous injection of morph. sulph. gr. ¼. The catheter was passed twice a day for two weeks, as she could not void her urine without change of position. Her bowels were kept quiet for one week after the operation. At the expiration of two weeks the small ligature around the mouth of the Fallopian tube came away, and some of the sutures were removed. At the end of the third week she sat up in bed, and at the expiration of a month she left the bed. The first of the large ligatures came away between three and four weeks after the operation, a second was removed after an interval of six weeks, and the third and last came away on the 29th December. The patient recovered from the operation without any drawback.

More than six months have now elapsed since the operation, and the patient enjoys perfect health; she says she has not been so well in years. There is no sign of any reproduction of the malignant growth, nor is there any trace of disease in the ovary of the other side. Certainly, if a malignant growth is ever entirely removed, this seemed to have been. The only unfortunate circumstance in connexion with the operation, and one that I do not remember to have seen mention-

ed in any case, is that within the last two months a small hernia has shown itself on the right side of the incision where one of the suture wires passed. As this did not show itself for four months, and not until the patient had been upon her feet, as usual, for six weeks or more, it seems evident that it can only be connected with the operation indirectly. A small pad, which she wears, suffices to keep the bowel in place.

April 29, 1867.

TWO CASES OF PENETRATING BAYONET WOUNDS OF THE CHEST.

By S. BARUCH, M.D.

Camden, S. C.

Case I.—Priv. Wm. Tintler was wounded in a bayonet charge on the 8th of May, 1864, at Spottsylvania C. H., Virginia. He was brought to the division infirmary an hour after reception of his wound. On examination, two apertures were discovered, one a triangular, ragged opening in the back, about one-half inch to the right of the tenth dorsal vertebra, and the other a small puncture, three inches below the right nipple, near the angle of the ninth rib.

He states that, as the charging line advanced with fixed bayonet, he was in a stooping posture, loading and firing rapidly. While thus engaged he was transfixed by a bayonet, and he asserts positively that he distinctly felt the withdrawal of the weapon.

When first brought to me, the following symptoms presented themselves: His face was pallid and anxious, nostrils distended; skin cool; pulse weak, but somewhat excited; breathing difficult and labored. There was slight oozing of blood from the posterior orifice, *which was contracted;* and bloody expectoration similar to that occurring in gunshot wounds of the lungs. These symptoms, conjoined with the direction of the wound and history of the case, led me to the belief that the right lung was transfixed. The "bent" position of the patient prevented implication of the right lobe of the liver, as in that posture the liver is separated from the diaphragm, and thus the bayonet avoided this organ.

May 9.—Patient expectorates bloody mucus, complains of pain in the right lung, has but little cough; shock has passed off and he is tranquil.

May 12.—Bloody expectoration ceased, but pain still continues. Auscultation and percussion reveal no signs of pneumonia or pleuritis.

May 13.—Posterior wound is healed over by scabbing. Still no symptoms of pneumonia.

May 16.—Patient is doing finely; there is some acceleration of the circulation and dyspnœa, but no *physical* symptom of lung disease.

May 17.—Sent to general hospital in fine spirits.

Case II.—Corporal G. Percival, a man of large frame and good constitution, was wounded in the same charge as Case I. His case was brought to my notice about three hours after the wound had been inflicted. Divesting him of his shirt, which had an opening in the back, I examined the chest carefully, and found two apertures of a triangular shape, one, the largest, in the back, just below the inferior angle of the left scapula, and the other, very small, over the sternum, near its right border, on a line with the fourth rib.

Patient was lying on his abdomen and partially on his left side, behind a small rail pile, when he was transfixed by a bayonet. When brought to the infirmary, his countenance was pale, but *did not* wear that expression of anxiety so peculiar in penetrating wounds of the chest; his symptoms indicated a shock to the nervous system, induced by the intense excitement incident to a hand-to-hand conflict. The whole system seemed to suffer from depression following great excitement. Acting on this view of the symptoms, I administered some stimulants and an anodyne, which partially restored the patient, and enabled him to recite his encounter.

Under perseverance of this treatment the pulse rallied, and skin became warm. There was but slight dyspnœa, no cough, and very little bloody expectoration; all indicating that the injury to the lungs was not extensive. A careful investigation of the posture of the patient during reception of the wound, and a consideration of its direction, convinced me that the weapon entered the back, grazing the right border of the posterior portion of the left lung, passing through the posterior mediastinum and invading the heart, which was displaced by the patient leaning somewhat on his left side.

May 9.—Patient has recovered from shock and nervous depression; this fact confirmed me in the belief that the lung was not seriously implicated, and that the heart and great vessels had escaped entirely. His countenance wears a more cheerful look; pulse somewhat excited, but it seems to be more of a nervous than febrile excitement. Very slight expectoration of bloody mucus, and he coughs only when he makes an effort to change his position.

May 11.—Doing well; dyspnœa inconsiderable, and no physical signs of pneumonic or pleuritic inflammation. His bowels having been costive, a mild cathartic was ordered.

May 16.—Still free from pulmonary inflammation; but he complains of pain in the epigastric and umbilical region. Emollient poultices were applied, and an anodyne administered at bedtime.

May 17.—Pain has discontinued, and patient is again in good spirits.

May 19.—Sent to general hospital. In the following July both of these patients were again on duty with their command.

Remarks.—Besides these cases, a number of others of a less serious nature presented themselves for treatment, nearly all of which recovered at the field infirmary and were returned to duty.

The limited experience derived from the treatment of these cases induces me to consider bayonet wounds as very simple injuries, readily healing by first intention, under favorable conditions.

Perfect tranquillity and continued application of cold water to the openings of exit and entrance are most essential. I found that the chest cases, though presenting a more extensive track than those of the hands, loins, shoulders, and hips, healed more rapidly, for this reason, that the slightly punctured patients would not obey my injunctions to keep quiet.

The sequelæ of bayonet wounds are not as serious as those of gunshot injuries. Not one of the men who received injuries of this kind, was rendered unfit for service. There was no exudation of superfluous lymph, no irregular gluing of muscular fibres, no permanent or even temporary contraction of muscles or tendons. Our knowledge of bayonet wounds has been so limited that their effects have been, until a recent period, involved in considerable doubt and even mystery. Experience, however, teaches that we have exaggerated the nature of these injuries, and attributed to them formidable qualities which they happily do not possess.

Why is it, that soldiers have such terrible fear of the

bayonet? Why is it that the determined approach of a line of glistening steel makes the cheek blanch and causes the bravest hearts to waver? Why do we in many battles witness the rout of lines that have unflinchingly withstood a continued galling fire of musketry and artillery, as soon as the opposing line approaches closely with fixed bayonets? This dread of "cold steel," is, in my humble opinion, mainly attributable to ignorance of the nature of the injuries inflicted by it. There appears to exist in the minds of men a vague dread of transfixion by the bayonet. But this would probably not be so, were it generally known that bayonet wounds are almost harmless, when compared to the ploughed tracks which the terrible minié bores through the tissues. The bayonet, on account of its less velocity, is easily diverted from a straight course by bony, cartilaginous, and tendinous tissues, and forms a smooth track, whilst the minié is relentless in its course, whirling with unimpeded force through all opposing structures, crushing, tearing, maiming all. A bayonet wound almost invariably heals by first intention under auspicious circumstances, and leaves no deformity behind, whilst the simplest ball wound requires weeks for a complete recovery, and then perhaps leaves the sufferer with a contracted and useless limb.

Original Lectures.

THE PRODUCTION OF MUSCULAR FORCE.

BEING REMARKS MADE

By Prof. J. C. DRAPER, M.D.,

AT NEW YORK MEDICAL JOURNAL ASSOCIATION.

MAY 31, 1867.

Mr. Chairman—Until a comparatively recent period, the opinion of Liebig that muscular force was the direct product and consequent of oxidation of muscle-fibre, was very generally received and adopted by the majority of physiologists of reputation. The urea of the urine was at the same time regarded as the result of this action, and therefore the quantity of this ingredient was supposed to be dependent on the degree of muscular activity. Impressed with this idea, about twelve years ago I undertook a series of experiments, in order to determine the amount of urea produced by various degrees of muscular action. The results of these experiments were altogether different from what was expected, and they were embodied in the form of a thesis, which was published in the *New York Journal of Medicine*, for February, 1856.

In this paper it was shown that there was no relation whatever between the quantities of urea and muscular action; and that a movement of thirteen miles on a level road, instead of producing an increase in the diurnal quantity of urea, actually caused a reduction; there being less urea secreted during the twenty-four hours in which the work was done, than during twenty-four hours in a state of rest, as is demonstrated by the following table:

	Quantity of Urine.	Solid Residue.	Urea.	1,000 of solid residue contain of Urea.
Standard,	1,106 cubic centimetres,	55·584 grs.	27·023 grs.	490.
Violent motion,	905 " "	52·081 "	25·472 "	488.

It had already been proved by Liehman, that variations in diet produced very great variations in the diurnal amount of urea, and I therefore concluded that urea was produced directly from the food, and was not the representative of muscular action; and that if muscle was disintegrated in order to produce force, the products of that disintegration were voided from the system by some other channel than the renal apparatus.

Bischoff and Voit soon after advocated the opinion that muscular force was not the product of the oxidation of muscular tissue; and the investigations of Edward Smith demonstrated that muscular activity increased the secretion of carbonic acid very considerably, while there was very little variation in the quantity of urea, as is shown in the following table:

Condition.	Carbonic Acid, per hour.
During sleep,	19 grains.
Lying down and sleep approaching,	28 "
Sitting posture,	29 "
Walking, rate 2 miles per hour,	705 "
" " 3 " "	1006 "

The doubt which was thus thrown on the theory of Liebig has been still further increased by the experiments of Drs. Fick and Wislicenus of Zurich, who advocated the opinion of Fraube, that muscular force is not in any degree dependent on the oxidation of muscular fibre, but is produced by the combustion of the hydrocarbons.

They regard a muscle-fibre as an apparatus or engine, in which hydrocarbons undergo oxidation, which results in the production of force and heat; and just as in an ordinary machine consisting of iron and steel, though the power is developed by the combustion of coal, there is a little wear and rust of the machine, so in muscle-fibre there is a similar small amount of disintegration of tissue, which may be represented by urea, or some other nitrogenized constituent of the urine.

The experiments on which these conclusions are based are of sufficient importance to justify a detailed account. They consisted in the ascent of one of the peaks of the Swiss Alps, known as the Faulhorn; the path chosen was the steepest that was practicable, and the height attained about 2,000 metres above the Lake of Brienze. In order to reduce the amount of urea to the lowest point, no nitrogenized food was taken for about eleven hours before the ascent was commenced. The average amount of nitrogen per hour during this period, which represented *night urine*, was for Fick, ·63 grains; for Wislicenus, ·61 grains.

The ascent was begun at $5\frac{19}{30}$ A.M., and was completed in about eight hours, during which time only hydrocarbons were taken as food. The excretion of nitrogen by the kidneys, was for Fick, ·41 grains, Wislicenus, ·39 grains per hour, and represented the *work urine*. The urine passed for five and a half hours after the completion of the ascent, and was also collected and designated as the *after-work urine*. It showed an excretion of nitrogen equivalent to ·40 grains per hour for Fick, and ·40 grains for Wislicenus. At the close of this period, which was at 7 P.M. on August 30th, a hearty meal, consisting mainly of nitrogenized food, was taken; and the urine of the succeeding ten and a half hours, *i. e.* to 5·30 A.M. of August 31st, collected. It gave for Fick ·45 grains, and for Wislicenus ·51 grains of nitrogen per hour, and represented the *after-work night urine*. Arranging these results in a tabular form we find:

Night urine,	Fick,	·63 grains.	Wislicenus,	·61 grains.
Work urine,	"	·41 "	"	·39 "
After work urine,	"	·40 "	"	·40 "
After work night urine,	"	·45 "	"	·51 "

During and after the period of labor the smallest

proportion of nitrogen was excreted, which agrees with the results that I published in the article previously mentioned.

On the data furnished by these results, Drs. Fick and Wislicenus argue that since Rauke and Shiry have shown that neither the perspiration nor the breath contained any appreciable amount of nitrogenized compounds, it would therefore appear that muscular force cannot be the product of disintegration of muscular tissue; but that the idea of Fraube is probably correct, and that we must regard the combustion of hydrocarbons as the true source of such force.

In order to place in a little stronger light the results obtained in their experiments, these gentlemen adduce an extended calculation to demonstrate that the oxidation of an amount of muscle-tissue equivalent to ·40 grains of nitrogen per hour, is altogether inadequate to the production of the power required to accomplish the work represented by the ascent of the mountain; and if the action of the heart and other muscles engaged in carrying on the functions of the body is taken into account, the work accomplished is at least three times greater than the utmost amount of force that could have been produced by the nitrogenized matter consumed. They therefore conclude, "that since the burning of nitrogenized material cannot be the only source of muscular power, it is not in any way concerned in its production; and considering the delicacy of a muscle-fibre it is not likely that different kinds of chemical processes should be employed to produce the same effect. Even steam-engines are not indifferent as to the material burned in them. In one made to burn wood, it would not do to use coal. How, then, is it possible to conceive that the muscle-machine was constructed especially to consume nitrogenized material, and that when enough is not to be had, it puts up contentedly with non-nitrogenized fuel? That it does make use of non-nitrogenized material, we have by our own experiment proved, beyond a doubt. We therefore conclude that, *since the muscle machine can be heated by means of the non-nitrogenized fuel, this fuel is in all cases that best suited for it.*"

For additional support to this doctrine, attention is drawn to the care with which the digestive apparatus of ruminants is adapted to the digestion of cellulose, a non-nitrogenized body; and to the fact that animals of great strength and swiftness subsist on food containing very little albuminous matter. The statement of Dr. Piccard is also cited, that the chamois-hunters of Switzerland, in their expeditions, take with them, as provisions, nothing but bacon-fat and sugar, having found by experience that they answer their purposes for a time better than meat.

The experiments of Dr. Zalesky, given in the *Lancet*, for March, 1866, show that on removing the kidneys the amount of urea in the blood is not increased, but on ligating the ureters it increases very rapidly, which goes to prove that urea is not the product of muscle disintegration, but is formed in the kidney. This conclusion favors the opinion of Fick and Wislicenus, that muscular force is the result of the oxidation of non-nitrogenized matter only, and that combustion of albuminoid bodies has nothing whatever to do with it.

Dr. Zalesky, in connection with these experiments, draws the important conclusion, that since the kidneys form the urea, the so-called uremic accidents that occur when the secretion is suppressed, are not due to the presence of urea in the blood, since that substance is not produced under such circumstances, but that the poisoning is the consequence of the non-separation of some of the constituents of the extractive group.

From this momentary digression we revert to the discussion of our subject, by referring to an article published in the *Philosophical Magazine* for Sept., 1866, by Professor Frankland, in which he first notices that the experiments of Fick and Wislicenus lose a portion of their importance on account of the fact that the amount of actual energy generated by the oxidation of a given weight of muscle in the human body, is unknown; and that there were no accurate data of the heat of combustion of muscle, nor of its nitrogenized residue, urea. This missing link Prof. Frankland proceeds to supply by means of a series of experiments with the calorimeter of Lewis Thompson; the combustion being accomplished by means of chlorate of potassa. The results are expressed in *heat units*, each of which is equal to one grain of water raised through 1°C of temperature, while the mechanical equivalent of heat is that of Joule, in which 1 kilog. of water raised 1°C, — 423 metre kilogs. They are as follows:

Substance dried at 100° C.	Average heat unit.	Average metre kilog of force.
Beef muscle washed with ether	5,108	2,161
Purified albumen	4,998	2,117
Beef fat	9,069	3,841
Hippuric acid	5,383	2,280
Uric acid	2,615	1,108
Urea	2,206	934

It is to be remembered that the amount of actual energy produced in the body is less than that given in the above table; for under these circumstances the oxidation is not complete, urea being produced instead of carbonic acid, water and nitrogen; and since dry muscle yields one-third its weight of urea, the amount of energy produced in the body can only be for "Beef muscle washed with ether," heat unit 4,368, metre kilogs of force, 1,848.

Applying this result to the experiments of Fick and Wislicenus, and allowing for the fact that probably at least half the oxidation was lost as heat, Prof. Frankland finds, that "scarcely one-fifth of the actual energy required for the work performed could be obtained from the amount of muscle consumed."

Though Prof. Frankland admits the truth and force of the experiments of Fick and Wislicenus, he by no means admits that non-nitrogenized articles alone are consumed to produce force; for he states that the nitrogenized also, inasmuch as they are combustibles, and consequently capable of furnishing actual energy, might be expected to be available for the same purpose; and such an expectation is confirmed by the experiments of Savory upon fats (*Lancet*, 1863, pages 381 and 412), which show that these animals can live for weeks in good health upon food consisting exclusively of "muscular fibre." The conclusions finally drawn from an extensive series of experiments are announced by Prof. Frankland as follows:—

"1st. A muscle is a machine for the conversion of potential energy into mechanical force.

"2d. The mechanical force of the muscles is derived chiefly, if not entirely, from the oxidation of matters contained in the blood, and not from the oxidation of the muscles themselves.

"3d. In man the chief materials used for the production of muscular power are non-nitrogenized; but nitrogenized matters can also be employed for the same purpose; and hence the greatly increased evolution of nitrogen under the influence of a flesh diet, even with no increase of muscular action.

"4th. Like every other part of the body the muscles are constantly being renewed, but this renewal is scarcely perceptibly more rapid during great muscular activity than during comparative quiescence.

"5th. After the supply of sufficient albuminoid mat-

ters in the food of man to provide for the necessary renewal of the tissues, the best materials for the production both of internal aud external work are non-nitrogenized matters, such as oil, fat, sugar, starch, gum, etc.

"6th. The non-nitrogenized matters of food which find their way into the blood, yield up all their potential energy as actual energy; the nitrogenized matters on the other hand leave the body with a portion, at least one-seventh, of their potential energy, unexpended.

"7th. The transformation of potential energy into muscular power is necessarily accompanied by the production of heat within the body, even when the muscular power is exerted externally. This is doubtless the chief, and probably the only source of animal heat."

Comparing these conclusions with those of Fick and Wislicenus, we find that while the first are stated at greater length, they only differ from the latter in supposing that nitrogenized substances can be and are employed in the muscles for the production of force.

In a paper on Insensible Perspiration, read before the Academy of Medicine, May, 1864, and which was based on a long series of experiments, I arrived at the conclusion, that the effete material arising during the production of muscular force, was evacuated as nitrogen, by the skin and lungs, and not as urea, by the kidneys. The experiments of Prof. Frankland do not militate against this opinion.

There still remains one element in the problem to be yet solved: it is the variation in the proportion of sulphates excreted during rest and motion. To this I hope to devote some time during the ensuing summer. If it is found that violent muscular action produces a corresponding increase in the amount of sulphates, it will tend to show that muscular tissue does undergo disintegration during the period of activity; while, if it is not materially increased, the conclusions of Fraube, Fick, and Wislicenus will be demonstrated beyond peradventure, and we shall be obliged to accept the doctrine that muscular action is the product of oxidation of non-nitrogenized material alone.

Cysticercus in the Brain.—Dr. John Harley reported (*Lancet*) an interesting case, in a pathological point of view, to the Medico-Chirurgical Society, illustrating the development of the larval form of the common tapeworm in the substance of the brain, about sixty cases of which are on record; the affection is, therefore, a rare one. The subject of the present case was a healthy boy, fifteen years old. He died of acute rheumatismal pericarditis and encephalitis, after a week's illness. Only a solitary larva was found in the body, and this was imbedded in the right corpus striatum and slightly projecting into the ventricle. The cyst was no larger than a pea, and contained within its interior the retracted head and neck of the parasite. The species was distinguished by the large size of the great curvature and the strong bases of their hooklets, and by the development of dark violet pigment granules about the hook sacs. The boy had always enjoyed good health, and the only evidence of cerebral disorder was manifested during the last two months of his life. It consisted of frontal headache and an uncontrollable tendency to sleep—symptoms which were probably caused by the presence of the parasite.

Wet-Nursing in France.—A petition has been presented to the French Senate asking that all mothers be compelled to nurse their own children.

Jager, the distinguished German oculist, recently died at Vienna, aged eighty-four years.

Reports of Hospitals.

JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

CLINICS OF PROF. GROSS.

OSTEO-MYELITIS—TRIPLE AMPUTATION IN CONTINUITY OF HUMERUS AND AT THE SHOULDER-JOINT.

Mrs. F——r, æt. 43, much older looking, very much emaciated by suffering, not weighing over 70 lbs., was sent to the clinic April 17, 1867, by Dr. K——r, for what was at first supposed to be an ordinary case of inflammation of the elbow-joint resulting in anchylosis, with more or less implication of the bone. Two years ago this patient fell upon the curbstone striking her left elbow, which had been stiff ever since the accident. The elbow was a good deal swollen, very painful, and presented a number of openings communicating with the articulation, from which there was a good deal of discharge; some spicula of bone had been discharged at times. The general health of the patient was not good, and she was suffering from the remains of a diarrhœa. The patient was ordered some tonic treatment, and told that were she strong enough, her arm would be amputated as the only means of procuring relief; but the poor woman begged so hard to have the limb removed at once, and thus be put out of suffering, that Prof. Gross consented to perform the operation. Chloroform was carefully administered, and at the moment of anæsthesia, the arm was removed by flap operation at its middle; but the moment the saw entered the bone it sank into the medullary cavity, showing that a more serious state of affairs was present than had been anticipated, and therefore on its removal, the stump was immediately amputated high up, without waiting to renew the anæsthesia, which had gone off. Here again the same condition prevailed, and it was found that the entire bone was diseased, whereupon a third amputation was immediately performed at the shoulder-joint, digital compression controlling the subclavian. This last was under peculiar difficulty from the extreme shortness of stump left by the two previous amputations. The flaps were taken from the wasted deltoid, and the great pectoral and broad dorsal muscles. The entire humerus was diseased, the head of the bone crushing under moderate compression between the thumb and forefinger. The glenoid cavity was not involved, and there was therefore hopes of recovery, if the patient should get over the shock, for the last two operations were not performed under anæsthesia.

The patient was placed under the influence of tincture of the chloride of iron with quinine, and milk punch, with a nutritious diet; and promptly recovered without a single untoward symptom, improving in flesh and strength during the union of the flaps.

FISTULE IN THE ANUS.

Wm. G——r, æt. 48, by trade a tailor, presented himself to the clinic, Dec. 29, 1866. About eleven weeks ago his attention was called to an anal abscess, which was very painful, and in about three weeks opened without surgical interference, the discharge not being very great. The result has been the formation of an anal fistule.

There are two kinds of abscesses at the verge of the anus; one is phlegmonous, similar to the abscess liable to form in any other part of the body. The symptoms of such an abscess are acute, well characterized, and the

pus is of a peculiar consistent character, containing an immense number of globules, comparatively little fatty matter, and it is of a whitish cream-like appearance. Then there is a strumous, scrofulous, tuberculous, or chronic abscess, which is liable to form in this situation in persons predisposed to consumption, or who are laboring under that affection, who labor under this peculiar strumous or scrofulous diathesis,—not liable to form in all persons any more than pulmonary consumption is liable to form in all constitutions. A person must have a predisposition to the formation of such an abscess, or else it could not take place, and it is frequently attended with a tuberculous deposition in the follicles of the mucous membrane of the rectum. This tubercular matter gradually softens, disorganization ensues, and at length an ulcer forms which becomes a source of irritation; this irritation is gradually transferred to the tissues around,—and finally there is gradually formed an abscess of the character mentioned. The patient before the class had, from the account given of his symptoms, a phlegmonous abscess, for he has not had cough, shortness of breath, night-sweats, or loss of flesh, and his tongue is clean, and his bowels regular.

In examining such a case, we insert a grooved director along the tract called the fistule, at the same time passing the finger of the other hand into the interior of the bowel; the patient being on his elbows and knees, the head low down, and the knees forward, the legs being widely separated; for in this manner the breech is fairly presented. The opening in the present instance is larger than the barrel of a goose-quill, and readily receives the point of the instrument, which passes readily into the rectum. There is but one track. It is therefore what we call a complete fistule in the anus.

There are two forms of *incomplete fistules* in the anus; one in which there is an external opening leading up to the bowel, but not into it, not passing through the wall of the bowel; this is called an external incomplete, or an external blind fistule:—then there is an internal fistule in which the opening passes from the interior of the bowel into the connecting cellular tissue around the tube, not communicating with the skin, and consequently not opening on the external surface; this is called an internal incomplete, or internal blind, or internal occult fistule.

The *complete fistule* is that variety most frequently met with, and here there is a direct passage from the external surface into the interior of the bowel. There may be but one external opening, or there may be two, three, five, or seven, so that the surface around presents a cubriform or perforated swivel-like appearance. Generally there is but one opening, which is either at the side, as in the present instance, or in front towards the scrotum, or behind towards the coccyx. When there are several external openings they generally communicate with the main sinus; but sometimes they open separately into the interior of the bowel. This internal opening is usually single; although sometimes there are two, sometimes three; but this is uncommon. Then, this internal opening is situated immediately above the internal sphincter muscle, at the height of about four and a half to six lines above the verge of the anus, sometimes not more than three lines; not situated high up, as was formerly supposed by the older pathologists and surgeons, at the distance of from one to two or three inches, but just above the verge of the anus.

In former times *the operation for anal fistule* was a most barbarous, cruel, and painful one, and even a dangerous one, in consequence of the supposition on the part of the surgeons, that the internal opening passed high up, for the bowel was slit open to that extent, a proceeding frequently dangerous on account of the resulting hæmorrhage, and the cure was always protracted in consequence of the severity of the operation. It remained for Kiper, an eminent French surgeon, to place this part of pathology in its true light, by showing that the internal aperture always exists just above the verge of the anus, or just above the true sphincter muscle at a distance from three to five lines, and sometimes, as an exception to the rule, even to the distance of an inch.

When there are a number of external openings, as not unfrequently happens in cases of long standing, then the parts are callous from interstitial deposits of plastic matter, usually more or less in a state of irritation, or even constant inflammation, attended with a great deal of discharge of mucus, and often fæcal matter.

The *diagnosis* of an affection of this kind can always be readily determined by a careful exploration of the bowel; the contents having been cleared out as a preliminary step by some slight laxative the previous evening, or by means of the enema.

If the patient be a female, she is placed upon the side in bed; if a male, in the position already described; the fore-finger, well oiled, is then carefully inserted, by a sort of rotary movement, into the bowel, and then by separating the parts, you look for the external opening, whose situation is frequently indicated by the existence of a little papule, a sort of nipple-shaped projection—nothing, however, but a mass of granulations; then you pass your probe into the centre of that, and at once it proceeds along into the main channel.

Performing the operation with a sharp probe-pointed bistoury, you introduce the finger into the bowel, then insinuate the probe-pointed bistoury along the fistule, and when the point of the instrument comes in contact with the finger in the bowel cut from within outwards, in this way withdrawing the finger and instrument at the same time.

This is not the way in which we now perform this operation. We employ here a process much more simple, and by which a man may operate in the dark without any difficulty. The grooved director is pushed through the fistule, and brought out across the opposite nates, exposing the whole thing, and then the trach is slit open with the knife.

As the case before us is a recent one, it is not necessary, after the operation, to pare the edges of the incision; an operation which should never be neglected when the parts are callous, indurated, and irregular. A well-oiled tent of patent lint is introduced into the wound with the object of making it heal from the bottom by the granulating process. The tent is to be retained for forty-eight hours and then removed, and it need not be replaced by a fresh one. The bowels should be locked up for at least three days, keeping the parts in a quiescent condition; then an enema may be administered, or what is generally preferable, a dose of castor-oil, or an ounce of sulphate of magnesia, or a portion of rochelle salts, etc.

The patient should observe great cleanliness, the parts should be washed after the removal of the tent several times in the twenty-four hours. The diet should be simple, nutritious, and not calculated to distend the alimentary canal habitually; and thus the treatment is continued until the patient gets well, in from a fortnight to a fortnight and a half after the operation.

A male infant, æt. 9 months, was brought to the clinic April 17, 1867, with an *anal fistule* which commenced three months previous in an abscess. There

were three external openings, one upon the right side and two upon the left, there being complete anal fistule upon each side. One of the fistules in the left side was divided, and the other was not disturbed, in the hope that repose of the sphincter would permit the other to heal up without interference.

This case is interesting on account of the tender age of the patient, for anal fistule rarely occurs so early in life.

Progress of Medical Science.

Bromide of Potassium in Functional Epilepsy.—Dr. C. L. Hubbell, of Troy, N. Y., in an article on some of the uses of bromide of potassium, published in the *Boston Med. and Surg. Jour.*, relates several cases of functional epilepsy treated by this salt. He administers it in solution, in the proportion of 3 i of the salt to three ounces of water, the dose being a teaspoonful after each meal.

The Treatment of Menorrhagia.—A recent number of the *Lancet* gives a very interesting account of the treatment of menorrhagia, as carried on by the gentlemen connected with the out-door department of the several London hospitals. When we take into account the number of organic troubles of which menorrhagia is but a symptom, we can easily conclude that its treatment must depend upon a variety of circumstances. The number of cases which present themselves, and the dispatch which is necessary in prescribing for such, has given rise to a certain routine, which, considering the practical results obtained, is of value.

Dr. Greenhalgh (St. Bartholomew's Hospital), assumes that the majority of cases of menorrhagia are due to fibroid, or fibrous out-growths or in-growths from the uterus. These are mostly treated by a pill composed of one-twelfth of a grain of bichloride of mercury combined with quinine and belladonna, to which are frequently added small quantities of the aqueous extract of aloes, taken night and morning for some weeks; a mixture composed of dilute sulphuric acid, tincture of Indian hemp, mucilage, liquid extract of ergot, syrup and infusion of quassia, three or four times a day, being ordered just prior to and during the catamenial flow. Between the "periods" a draught of iodide or bromide of potass, with the liquid extract of ergot, sal volatile, and infusion of quassia, is given twice a day. If the loss of blood has been very great, or the patient be anæmic, the tincture of sesquichloride of iron with the liquid extract of ergot, chloric ether, syrup, and infusion of quassia, twice or thrice a day, with the pills, are prescribed. Where the patient is more or less plethoric, which is rarely the case, the sulphate of magnesia and digitalis, either with dilute sulphuric acid or salines, and scarifications or leechings of the cervix uteri, are found most serviceable. In cases of subinvolution of the uterus, attended with menorrhagia due to imperfect recovery from labor or miscarriage, hyperlactation, or other affections leading to constitutional debility, especially in the strumous habit, the syrup of the iodide of iron, with or without ergot, and with the pill above referred to, are found very efficacious. A similar course is pursued, sometimes with, sometimes without, the pills, where the commencement of malignant disease is the exciting cause of this symptom. In cases of Bright's disease and other affections interfering with the stasis of the blood, gallic or tannic acid, usually combined with henbane, prove valuable hæmostatics; some preparation of iron with arsenic being usually ordered between the "periods." Where polypi, portions of retained ovum, or fibrinous clots are detected, they are removed.

Dr. Greenhalgh particularly draws attention to the frequency of menorrhagia as the result of collections of fæcal matter in the large intestines and rectum, and of hepatic derangements occasioning mechanical irritation and congestions of the hæmorrhoidal vessels and uterus. For calculi, in addition to the pills, he prescribes repeated doses of the compound decoction of aloes, with tincture of nux vomica.

In all cases he recommends quiet of mind and body; rest in the recumbent posture; nutritious and unstimulating diet; cold acid drinks; tepid or cold water vaginal injections; great moderation or total abstinence from sexual excitement. He now and then has recourse to the following means:—Matico-cotton plugs or pessaries; astringent vaginal injections; sponge tents; iodide of lead, and atropine pessaries; iodised cotton; Hodge's and other pessaries in cases of misplacements of the uterus, etc.

Dr. Greenhalgh adds that, *cæteris paribus*, menorrhagia is more prevalent among women of lax fibre, more especially if they have had many children or abortions, in rapid succession; in those subject to acne, pruritus, or eczema, and about the climacteric; in those of intemperate habits of various kinds, etc. He considers it is by no means always easy to determine whether the case is one of menorrhagia or threatened abortion.

Dr. Grailly Hewitt (University College Hospital) has little faith in mere palliative remedies, but thinks that the treatment should be mainly directed to remedying the organic conditions which he considers are almost invariably present. He does not, however, underrate the cold vaginal douche, rest during the period, and the administration of ferruginous compounds, and also ergot in powders (3 ss three times a day).

Dr. Murray (Great Northern Hospital) is in the habit of treating functional menorrhagia by the combined use of gallic (grs. v–x) and dilute sulphuric acids (gtt. xv–xxv), principally with as much rest as can be obtained. This treatment may continue for a period extending over two months. He has occasionally found mustard over the sacrum every other night, or even a blister, of service in that form where after childbearing a large uterus, with a patulous os, is continually pouring out blood, and every now and then doing so in gushes, accompanied with clots. He also advises the application of cold water in the lower part of the spine in cases of continued discharge (not leucorrhœal) between the periods. He has not found the use of iron at all satisfactory. Enemata of cold water have been useful, especially at those moments when the gushes of blood with clots take place, a gentle non-irritating purgative being also given.

Dr. Parson (Charing-Cross Hospital) favors an astringent mixture composed of tannic acid (5 to 10 grains), dilute sulphuric acid (10 to 30 minims), and the fluid ext. of ergot of the British Pharmacopœia (5 to 10 min.), every four or five hours for the first few days. If there is much pain, 5 to 10 minims of tinct. of Indian hemp are added to each dose. Iron is only administered when the tendency to excessive flow has ceased.

The treatment employed by the above physicians applies of course mainly to functional menorrhagia; but when the discharge is dependent upon organic troubles the indications depend upon the character of the lesion that may be present, the satisfactory termination of the case depending in all such instances upon the removal of the cause.

Oil of Petroleum, says the *Union Médicale*, is a powerful agent for the destruction of insects. The crude

oil is the best for the purpose. A few *grammes* of petroleum diluted with water, and sprinkled by means of a watering-pot over strawberry plants, destroys the *maus*, or "white worm of the beetle" which infests those plants. The crude oil mingled with a large proportion of water is a sure poison for crickets. The mixture is to be poured through a funnel into the holes frequented by them. The *acarus scabiei* is very promptly and radically destroyed by inunctions with the oil. Frictions with petroleum water (60 gr. par litre) immediately cleanse the domestic animals of the parasitic insects which annoy them. The animals should be washed with soapsuds a few minutes after the friction. It is also stated that a house infested with rats and mice was freed from these guests a little while after the introduction of a large quantity of the oil into the cellar.—*Boston Med. and Surg. Journal.*

Chloroform to the Dying.—Dr. Joseph Buller, Physician to the Royal South Hants Infirmary, in an article with the above caption in the *British Medical Journal*, makes some interesting remarks upon the propriety of administering chloroform to the dying. The cases to which its use, in his opinion, seems applicable, are those in which there are extreme restlessness and sleeplessness, accompanying the exhaustion of the last days or weeks of the life of the very aged, especially when (as is often the case) the mental consciousness is still active and the failure of power in the vital organs is actually felt, with none of that physical courage to bear the suffering which the same patients had when younger and stronger. At this time opiates seem useless; in fact, all efforts towards alleviation of the distressing symptoms seem utterly futile without the anæsthetic. From some cases that he records as having come under his personal observation, it would seem that the chloroform, properly regulated, acted as a nerve stimulant, quieting pain, but still not interfering with the process of intellection.

Extraction of a Glass Bottle from the Rectum.—The following remarkable case was admitted into Darlington Hospital, under the care of Dr. Howison:

T. W——, aged thirty, a workman in the gas-house, was with some companions amusing himself with jumping over bottles placed above each other with their small ends uppermost. After he had in his turn jumped over the bottles, the top one was missing, and it appeared to have passed through a thin pair of flannel trousers into the rectum. The man, a patient of Dr. Howison, was brought to the hospital next morning. He gave very little appearance of anything being the matter. Immediately after the accident he felt very sick and faint. He went to bed, after trying to protrude the bottle. On his admission, the base of the bottle was found at the extremity of the ascending colon, though, from his description of its situation, soon after the accident, it was just about the junction of the transverse and descending colon. An injection of warm soap and water was at once given. This had the effect of bringing the bottle within extreme reach of the finger. Dr. Marion Sims' vaginal speculum was used to expand the rectum, and after several attempts to seize and draw it out by a pair of œsophageal forceps, it was at length expelled in a great measure by the action of the bowel, assisted by manipulation. With the exception of the pain experienced in expanding the rectum, the extraction gave the patient little uneasiness, and he walked home seemingly very little the worse. He was directed to remain in bed for a day, and very soon recovered. The bottle is a castor-oil bottle, such as is usually sold by druggists, and is eight inches long, four inches round at the thick extremity, and one inch and a half round the neck. It is rather curious that the bottle should have been plumped down upon so exactly at the anal orifice as to pass up without much pain. What the consequences would have been had the bottle broken in its passage, it is rather unpleasant to conjecture.—*Lancet.*

An Ingenious Bullet Detector.—A very ingenious piece of mechanism for the detection and extraction of bullets in wounds has been devised by Mr. Sylvan De Wilde. It seems that at the time Garibaldi was suffering from the effects of an undetected bullet in his limb, and pained by the fruitless efforts of operators to detect it, it occurred to several individuals of a philosophic turn of mind that electricity might very well be employed in the detection of metallic substances lodged within the human tissues. In France, M. Edmond Langlois, M. Favre, and Dr. Lecompte of the French Army Medical School at Val-de-Grâce, assisted by M. Rhumkoff, all made use of it in the elaboration of suggestions on the point. There is this manifest advantage, that the structures of the body are non-conductive—a fact that renders the action of the electric current more perfect.

Mr. De Wilde has apparently produced the most practical result: and his instruments have been submitted to the naval and military authorities, who have made a complimentary report about them. The apparatus consists of a probe and forceps, a battery, and an alarum, contained in a box eleven inches long by three broad, and two inches and a half deep. The elements for the generation of a current, which remains constant for some weeks, are zinc and carbon. The probe, consisting of two steel wires, insulated from each other, is connected with an electric horse-shoe magnet and a bell, and when (introduced into the wound) it touches the bullet the circle is completed, and the bell rings. The forceps act on the same principle, and are intended first to detect, then to seize, the bullet. They have curved points, and not pallets or spoons. The points of the probe are kept sheathed on introduction to a wound, and not uncovered till the supposed bullet is felt. This is effected by means of a sliding tube. The advantages of Mr. De Wilde's probe over others of its kind are very marked, and the army and navy officers will no doubt find it a great aid. The probe is a sensitive artificial finger, which enters deeply into the tissues, and gives the signal at once when it detects the hidden source of mischief below.—*Lancet.*

Puerperal Peritonitis treated hypodermically with Morphine.—J. H. Beech, M.D., in the *Detroit Review of Medicine and Pharmacy*, after relating the history of a case of Puerperal Peritonitis, says: "Having seen no report of hypodermic treatment of Puerperal Peritonitis, I conceive that this may encourage others to give it a trial. It will be observed" (in the history above mentioned), "that no efficient medicines were retainable by the stomach, except hyd. chl. mit. grs. iij. and morph. sulph. gr. i. very early in the attack, and no efficient use of enemata was secured until the danger had subsided, while the effect of the hypodermic injections was well marked and salutary. Do others find that this method of using morphia constipates, or even restrains the bowels? Some other cases have led me to think that it affects them very little, if any."

Tetanus Caused by Subcutaneous Injections of Quinia.—The *Gazette Hebdomadaire*, of the 28th June, mentions that two patients, one an adult and the other a child, died recently from the effects of quinia injected subcutaneously for the cure of intermittent fever. The same journal also alludes to a case of tetanus attributed to the same cause, reported in the *Southern Journal of Medical Sciences*, and copied into a British journal.

PRESCRIBING APOTHECARIES.

EVERY young graduate who, for the first time, feels that he is legally entitled to the appellation of Doctor of Medicine, rightly concludes that he by it should be distinguished from others not so fortunate. When, however, he has become engaged in the active duties of his profession, he is very soon undeceived, and becomes aware that the title is an exceedingly cheap one; that the man who concocts some patent vegetable pills with singular cure-all properties, who manufactures a hair-dye, a pile ointment, a youthful invigorator "for declining manhood," or who invokes the aid of spirits in the selection of a particular herb to meet his patient's case, or who is content to dispel disease by some miraculous touch, is not by name to be distinguished from him. But there is even a comfort in the thought that all such are the most pitiable of charlatans, and that the motives which actuate them in the performance of such deeds are either pardonable on account of the imbecility of which they are the offspring, or are in their wickedness too despicable for honest contemplation. He is in fact prepared to pity the one or despise the other; and in this he is upheld by the sensible portion of the general community.

There is, however, a distinct class of these pretenders to the title who, from their position, are more apt, by a too credulous people, to be voted the right to use the trademark of the profession and stamp the same upon all their doings; we refer to the apothecaries. If any one would undertake to examine into their motives for appropriating the name and assuming the privileges of the well-qualified and licensed physician, it would not be found very difficult to arrive at a result by no means creditable to the probity of the guilty party.

A well-educated and well-behaved apothecary is so indispensable to the physician, and the mutual relations which should exist between the two are so peculiar, that they cannot, in the interest of both, be too jealously guarded. For the most part, the regular pharmaceutists are men of integrity, learning, and sterling worth, but they form altogether too small a majority.

We do not propose to canvass all the little devices which our druggists are guilty of to catch a penny, or the very questionable and reprehensible little practices of abetting quack advertisements, and sundry other little things which they so naïvely acknowledge to be "tricks of the trade," but we cannot longer delay a reference to a practice which is as rife among them as it is disgraceful, viz. that of prescribing for those who may call at their shops for advice.

As soon as the merest shop-boy becomes employed around a drug-store, he earns for himself the appellation of doctor, and is at once looked upon by his associates and acquaintances as one versed in the arts of cure. He is at first staggered with the title, but as the simple result of being in the habit of hearing it coupled with his name, he becomes so accustomed to it that he tacitly acknowledges his right to it, and commences to govern his acts accordingly. After he graduates from his first position and is able to compound a prescription, his title becomes unquestioned, and whenever occasion offers he embarks in the practice of physic with an audacity that is really amusing. The very excellent opportunities they have of flattering a dangerous pride are too great for most of these so-called "drug-store doctors" to withstand, of giving a little advice along with a little medicine, and not unfrequently they become the Courts of Appeal for a patient who may not exactly understand why his physician prescribes this or that article.

We speak advisedly when we affirm that the number of shops in this city in which this abominable, disgraceful, unprofessional, and dishonorable practice of indiscriminate prescribing is forbidden, can perhaps be fixed at a dozen or two. The time has come when a physician can hardly enter any of these so-called respectable metropolitan stores without his professional character being insulted by the most impudent and ignorant pretensions of some stripling knight of the pestle, who does not hesitate, under any circumstances, to prescribe for anything which may come along; and if perchance he should insist upon the propriety of seeing the patient first, and not run the trifling risk, so to speak, of taking the word of a messenger, it is a species of refinement in drug-store practice very seldom indulged in. This statement would under ordinary circumstances appear paradoxical in view of the oft-repeated assertions of these individuals concerning professional honor, and other similar phrases, of which they are nowadays so willingly ignorant.

We are inclined to be charitable enough to suppose that it is not altogether the fault of these prescribers that they have patients; in other words, that they hardly solicit patronage; but when we have said thus much, we have given them all the extenuation which they deserve. When we contemplate the deliberate act for which they alone are accountable, that of complying with what, on the face of it, is a request they know is improper, our charity for the apothecary fails us. He

may be solicited to give advice; but knowing, as he must, that the giving of it is wrong, not only to his would-be patient, but to the profession whose confidence he outrages, he has no excuse to urge for so doing.

There are many aspects in which this subject of indiscriminate prescribing may be viewed in relation to the injurious influence it must exert upon the profession, not the least of which is the cheapening of the services of competent physicians—men who have to depend for a living upon professional fees, and who have, perhaps unfortunately for themselves, no drugs to dispose of, and thus strike a balance to their credit. Many apothecaries are wont to swell their honest bosoms with proud contempt at the idea that many physicians would stoop so low as to receive a percentage upon their prescriptions, yet while making these pharisaical demonstrations, they are cheating the honest practitioner out of many a legitimate fee.

If our apothecaries were educated to prescribe, as is the case with those of Great Britain, for instance, the matter could safely be trusted in their hands; a certain class of cases would then naturally drift into their way, and no one would be injured. But as the case now stands, these individuals are practising under false pretences; and on account of this, and of the evils which naturally grow out of it, the professional man has a right to demur.

It will be perceived, by reference to the action recently taken by the East River Medical Association, that a movement is about being made in the right direction by calling the attention of apothecaries to the impropriety and danger of repeating prescriptions without the physician's authority. Let them heed this, and the next step will be expostulation against the appropriation for their own purposes of the prescriptions of such physicians as may send their patients to their shops. These recipes are too frequently used as specifics for certain diseases, and the patients are made aware of the fact that this is Dr. A's or B's favorite recipe for a particular disease. If this practice were confined to a few of the drug-stores, it would hardly be a matter of much importance; but considering its great prevalence, it becomes the profession to concern itself in reference to some practical measures for protection against such fraudulent dealings.

We have received a copy of a circular which has been addressed to all Universities, Colleges, Schools of Medicine, and Medical Societies in Canada, requesting them to send delegates to a convention which is to assemble at Quebec on the 9th day of October next, for the purpose of aiding and coöperating in "the protection of the interests, the advancement of the knowledge, and the extension of the usefulness of the medical profession of Canada."

As the Union of the Provinces of Canada, Nova Scotia, and New Brunswick, is effected, and united Legislative and Executive action thus secured, it seems essential that there should also be uniformity in the laws which regulate life and health, and especially those relating to the exercise of the medical profession, Accordingly, at a meeting of the medical profession, held on the 18th of June last, at the "Laval University" in the city of Quebec, the following action was had:

Resolved, 1. That in the interest of the public, and the medical profession, it is desirable to adopt such means as will insure a uniform system of granting license to practice Medicine, Surgery, and Midwifery, throughout the Dominion of Canada.

Resolved, 2. That in future, all medical degrees or diplomas, of Universities, Colleges, or Schools of Medicine, shall have merely an honorary value, and licenses to practise Medicine, Surgery, or Midwifery, in the Dominion of Canada, shall be granted by a Central Board of Examiners, in each Province, before whom all holders of Degrees in Medicine, or Diplomas for Surgery or Midwifery, shall appear for examination.

Resolved, 3. That a committee of seven members be named by the Medical Society, to confer with the various Universities, Colleges, and Medical Schools in Canada, on the subject of the establishment of a Central Board of Examiners, before which all candidates for license to practise medicine in the Dominion of Canada shall be examiued.

Resolved, 4. That the Quebec Medical Society recommends the calling of a Convention of Medical Delegates, from Universities, Colleges, Schools, Medical Societies, &c., in the Dominion of Canada; to meet at the city of Quebec, on the second Wednesday in October, 1867, for the purpose of adopting some concerted action, on the subject of medical legislation, in conformity with this report, and for the formation of a "Canadian Medical Association."

The whole respectfully submitted.

W. Marsden, M.D., Chairman.
R. H. Russell, M.D., Secretary.

Laval University. Quebec, 18th June, 1867.

The above resolutions were unanimously adopted, and are to be submitted to the medical profession of Canada, at the proposed Convention in October next.

There is a movement also on foot in Canada to establish an efficient and general system of quarantine in accordance with the enlightened views of the authorities on the subject, and in keeping with those already expressed in these columns. As under the "Federal Union" of Canada the quarantine and marine laws will necessarily come under the federal control, and not the provincial and municipal, as unfortunately is the case in the United States, we trust that it will be adopted by the Central Government; and we know no person whose qualifications so preëminently fit him to be placed at the head of Quarantine and the sanitary laws of the kingdom, as William Marsden, M.D., of Quebec. His long and invaluable services in connexion with these subjects, both in Canada and the United States, richly entitle him to such distinction; and we are satisfied not only that the medical profession of Canada, but of our whole country, would hail such an appointment with approbation as one most fit and proper to be made.

Reviews.

TREATMENT OF FRACTURES OF THE LOWER EXTREMITY BY THE USE OF THE ANTERIOR SUSPENSORY APPARATUS. By N. R. SMITH, M.D., Professor of Surgery in the University of Maryland. Baltimore: Kelly & Piet. 1867. 8vo. pp. 70.

THE purpose of the monograph before us is to illustrate the good effects of a particular kind of treatment of fractures of the lower extremities, more particularly of the thigh, as well as other injuries of those parts which require absolute rest. The profession during the past few years has had presented to it, by American Surgeons, many devices for the accomplishment of this end, and many of them are, as has been abundantly proved by experience, excellent of their kind. In fact, the proper treatment of fractures has become an American specialty; and by foreign surgeons our results have been considered so surprisingly good, that they are willing to be instructed by us in this most important department of our healing art. The investigations into the nature of the injuries have been so carefully made, and the ingenuity of the American has been so often taxed to meet the indications, that it would be remarkable if great progress had not been attained by us in this branch. But of the number of splints that have been invented, while they plainly show a fertility of resource that is remarkable, comparatively few have outlived the test of experience in their employment. In this latter respect, Prof. Smith's will hardly prove to be a notable exception.

Let us in a cursory review of the contents of this little book ascertain for ourselves the soundness of those views upon which the author founds his practice.

The author, in the first place, affirms that there is a source of deformity and shortening, especially in fractures of the thigh, which has been very much overlooked; and that is a tendency in all such injuries, when the patient is in a recumbent position of the trunk, to slide toward the foot of the bed. This is partly attributable to the yielding of the bed, and partly to the impossibility of fixing the trunk and limb in a relatively immutable posture, without the most intense suffering on the part of the patient. The proper relations of the trunk with the fractured limb being then lost, it naturally follows that the fragments are proportionately disturbed in such a way that the upper one is made to overlap the lower. Assuming this to be true, which he claims he has a right to do from oft-repeated and careful observations, he maintains that "the objects to be attained in fractures of the lower extremity are: 1st. To furnish a surface of support which shall be accurately and permanently adapted to the surface and form of the limb which reposes on it. 2d. To so adapt the surface of the support, as that the limb sinking into it shall maintain its form by its own weight, without the necessity of any lashings here and there to secure it to the rigid portions of the apparatus. 3d. To make the limb obedient to all the unavoidable movements of the trunk, so that the upper fragment shall not by jammed upon the lower, nor contorted in relation to it by the movements of the trunk. 4th. To obviate the contraction of the muscles by the employment of an extending force, uniform in its action, easily graduated, and not requiring the application of bands to the ankle. 5th. So to arrange the supports, that in compound fractures we may have free access to the seat of injury, without removing any of the essential supports of the limb. 6th. To effect these objects by an apparatus simple in construction, capable of being anywhere procured, easy of application, not requiring to be reädjusted, and of but trifling expense."

Thus much having been said concerning the uses of the apparatus, its construction and mode of application may next be considered, in so far as they may tend to verify the truth of the assertions. A single splint constructed of iron wire for a framework, upon which muslin is stretched, forms the whole of the rigid, or supporting part, of the contrivance. The surface of the splint is flat, and has the shape of a long parallelogram, being bent in three different portions of its course, at angles to correspond with the upper flexures of the ankle, knee, and hip joints, these angles being modified according to the special indications growing out of the position of the fracture; the main idea being to accommodate the position of the distal fragment with the proximal one. The required position having been obtained, the splint is applied on the upper suface of the limb, and secured by the wet bandages, encircling it severally as follows: one above the ankle, one above and one below the knee, and one on the upper portion of the thigh. The suspending apparatus is next to be applied. As the degree of obliquity of the suspending cord in relation to the position of limb is said to have a great deal to do with the degree and direction of the extension employed, Professor Smith is very particular upon the point. Before proceeding further, we give the description of this portion of the splint in his own words:—"A small iron pulley is to be screwed into the ceiling, over the bed of the patient, perpendicularly over the middle of the skin, or nearly so. A cord about as thick as the wire of the splint passes over the pulley, and is reeved through a small tent-block, by which, slipping it upwards or downwards, we elevate or depress the limb. The eccentric pressure prevents the weight of the limb from causing it to slip; if not, rub it with chalk. This single cord, which depends from the block, has a loop at its end about two feet or more above the limb. Through this, another cord about five feet long passes, and hangs double from the loop by its centre. Each end has a hook attached to it, and when everything is ready they are hooked in appropriate loops in the cross-bars which are situated at different portions of the splint. Now, as to the points of attachment of these hooks, the author maintains that it is of great importance, in order that the centre of gravity of the limb be properly adjusted, and gives numerous directions as to how this can best be done. Lastly, the roller bandage is applied; and in order to complete the application of the principle, the extending or counter-extending forces, all that is necessary is "to move the bed of the patient "headways.'"

Having thus given the author's views, let us look at the other side of the question.

The first objection which can be raised against the splint is, that it maintains the limb in a more or less flexed position. It is now pretty well settled by the majority of the authorities upon the subject, that such a position has too many disadvantages attached to it to bear a strong recommendation, and it seems to us that our author hazards a great deal when he so boldly departs from an accepted rule without giving any better reasons than he does for so doing. His arguments would appear sound enough if we were willing to accept his premises. In starting with the assertion that the upper fragment of a fracture of the thigh, for instance, is tilted up by the action of the flexors, he assumes that, in order to get the two ends of the bones in proper position, the distal fragment must be brought up to the proximal one. Now, it strikes us that under ordinary circumstances, the more the thigh is flexed upon the pelvis, the greater the chance will be of tilting the fragment further forward; for, by relaxing the quadriceps extensor, the extremity of the fragment loses much of

that support which it would otherwise have. These muscles of the thigh, acting as so many natural splints, help to counteract, in no small degree, the action of the psoas and iliacus internus muscles. His object is also to give a uniform support to the limb without "lashings." But is this accomplished? Suppose a limb is suspended in the splint as proposed, what is the inevitable result? The weight of it upon the bandages causes a more or less extension of the fabric, and the limb sinks into them. If it did nothing more than this, the support might be equable and agreeable; but it is not likely to stop here. The limb, having lost its continuity at the point of fracture, is not apt to keep itself in line, and its whole weight is apt to be felt upon the weakest point; and as the result, there is a bowing backwards of the fragments. We speak advisedly when we say that this has occurred in numerous instances in which the splint has been tried, and especially has it been noted in cases of compound fractures, in which the opening being posteriorly, even the small support of sound tissue in that locality is lost.

It is true that the limb suspended in the apparatus is more or less obedient to the movements of the body, but this apparent good is more than counterbalanced by the resulting evil; for the splint being attached in common to the limb and the pelvis, we have a right to inquire how the extension is to be effected. We have, it is true, an apology for extension in the degree of the obliquity of the suspending cord; but how does it act upon the fracture? The two extremities of the bone are as firmly held together as bandage and iron wire can keep them, and steadied with firm, if not unyielding, appliances to the trunk. The extension is in reality exerted upon the abdomen of the patient, while the counter-extension is effected by the weight of the rest of the body upon the bed.

Even if the contrivance would admit theoretically or practically of extension, we cannot see what advantage the flexed position could have upon the straight. For by the former we shorten the distance between a muscle given to contraction, and at the same time virtually lift up the distal end of the proximal fragment by depriving it of the support of the natural muscular splints. In the straight position, when extension is properly made, everything is taken advantage of; the extensors are put upon the stretch, and help to pull down the tilting fragment, while that same force continuing and the fragment being proportionably braced, extension is next felt upon the psoas and iliacus internal muscles, and they eventually become wearied out, and give way.

The advantage of free access being afforded to parts, the subject of compound fracture, is something to take into account; but, for reasons already stated, the straight position would be the far preferable one.

The claim of simplicity of the apparatus is not to our mind so well established when we take into account the many necessary little fixings which must be attended to—the procuring of the splint in the first place, its bending, then the care of applying it, and last but not least, the inconvenience of attaching the whole to the ceiling. Whatever may be claimed by our author for the splint on practical grounds, he can hardly urge the one of simplicity as a recommendation for favor.

As a whole, we hardly think that the views of the author will commend themselves for the adoption of practising surgeons. The whole work bears evidence of special pleading in favor of an apparatus which the professor believes is unequalled; and although his convictions are stated in that good faith which should characterize every true worker in some new field of investigation, they lose all their force when the arguments for their support are candidly examined. We doubt not that in Professor Smith's hands the apparatus has done well; but its defects in arrangement and principle of action have doubtless been so modified by his own peculiar surgical skill, that we can hardly expect its employment to be attended with equal good results in less proficient hands.

From considerable experience in the treatment of fractures of the thigh by the straight position, we confess ourselves prejudiced in favor of it, but not so strongly as not to be open to conviction and change; but Professor Smith's work, far from altering our opinion, tends only to confirm it.

Reports of Societies.

N. Y. PATHOLOGICAL SOCIETY.

STATED MEETING, June 12, 1867.

DR. H. B. SANDS, PRESIDENT, in the Chair.

CANCEROUS LIVER AND SPLEEN.

DR. CUTTER presented a specimen of cancerous liver and spleen, accompanied with the following history:

June 2d, was called to see Mrs. D., age 53 years 9 months, who was said to be suffering from a tumor in the abdomen.

I found my patient confined to her bed, very much emaciated, with that peculiar countenance indicative of cancer.

Upon making an examination of the abdomen I found a large tumor in the epigastric region, which pulsated strongly, had a bruit and a thrill which were no longer discovered when the tumor was lifted from the aorta.

She at the same time drew my attention to a "wind tumor," as she termed it, in the right iliac region; it was not very prominent; fluctuation was distinct; and the feel was very peculiar, as if the wall of the cyst were composed of parchment.

I took it at once to be a cyst of the ovary until, she informed me that it had existed since she was ten years of age.

At that time she had had intermittent fever for about ten months; this made its appearance shortly after; it was described as an "ague cake," occupying the abdomen high up on the right side.

Eighteen years ago it suddenly fell into the pelvis; this was attended with great pain for about 48 hours. Should she arise suddenly or move about without stays or support she would suffer greatly with colic. Otherwise it has given her no inconvenience since.

The first symptoms of her disease began about six months ago.

The first complaint was a sense of uneasiness at the pit of the stomach, which came on without fever or other illness, and was always aggravated by taking food. This uneasiness was attended with impairment of appetite and with flatulence, heartburn, etc.

Vomiting was more or less prominent from the beginning to the end of the disease. The four days previous to her death she took no nourishment by the stomach, but having an *incessant* thirst, she drank cold ice-water in large quantities, and vomited *immediately* after each draught.

She had not a particle of pain from the first appearance of the disease to its termination, and died worn out by want of nourishment and broken rest, about six months after the disease first appeared.

The tumor presenting such a peculiar appearance, and the doctor not having had an opportunity to examine thoroughly into its condition, a committee was appoint-

ed, composed of himself and Dr. Rogers, to report upon the same at the next meeting.

SPONTANEOUS AND DIFFUSE OSTEO-MYELITIS.

Dr. Louis Bauer gave the history and exhibited the specimen of a case of spontaneous and diffuse osteo-myelitis, caries of the tibio-tarsal and intertarsal articulations, and multilocular abscess.

The patient belongs to a very healthy family. Since her infancy she has herself been of delicate constitution with a strongly marked nervous temperament, though never before so sick as to require medical attendance. In August last she was attacked with rigor and subsequent fever. The attending physician regarded the same as intermittent, and prescribed the ordinary remedies, to which it readily yielded. A few days after, he noticed a circumscribed swelling at the middle and in front of the left leg and another at the inner side of the corresponding ankle-joint, which rapidly matured into an abscess. The pain attending their formation was but insignificant, and the general health was scarcely disturbed. No cause could be assigned for the existing trouble.

On the 9th of September the patient was transferred to the care of Dr. Bauer. On examination the patient appeared very much excited and adverse to being disturbed. Her pulse ran as high as 116 per minute; there was, however, no increase of temperature or derangement of the vital functions. Appetite, alvine and urinary discharges were in the best order.

At the inner surface of the tibia there was a small aperture, surrounded by moderate thickening of the alveolar tissue. Its discharge was of a sero-purulent character and moderate in quantity. There was a similar opening at the ankle-joint with more circumferential intumescence, etc. Both leg and foot were œdematous.

Except the accelerated pulse, none of the appearances denoted an aggravated condition of the patient, and that might be satisfactorily explained by the excitement and the prevailing anæmia. However, it was deemed proper to examine the fistulous openings under anæsthesia, to ascertain the condition of the osseous structure in order to form a clear diagnosis. At the upper one the tibia was found to be bare and rough to an inconsiderable extent. The lower aperture led directly into the joint and the probe touched bare bone. The serious character of the complaint was thus fully established. So obscure as to the cause, so difficult was it to ascertain the relation of the co-existing affections. To all appearance, the two abscesses had formed contemporaneously; but there were no indications of an anatomical connection.

Liberal diet and proper hygiene were insisted on, quinine with iron prescribed, and the affected limb fermented and bathed with an infusion of chamomile.

Thus had the case proceeded a fortnight, when diarrhœa rendered the discontinuance of the iron and the use of opium necessary. Shortly after, medication had altogether to be suspended on account of gastric derangement. Scarcely had this been done, when a cold abscess at the left hip formed. Being evacuated by puncture, its contents proved to be pus, which measured about from six to eight ounces. Quinine was of course resumed. It is worthy of note that the suspension of that remedy on two more occasions was again followed by abscesses, respectively at the right infra-clavicular space and the right hip. On none of these occasions was there any constitutional aggravation; nor did the abscesses cause the slightest inconvenience to the patient during their ephemeral existence.

The latter part of the existing trouble offered very little material for clinical observation. The fistulous openings became of course more numerous along the lower half of the tibia and around the ankle-joint; the integuments of the leg, and particularly about the tarsus, were greatly swollen, infiltrated, and hardened. Though a flat shell of newly-formed bone was eliminated from the upper part of the tibia, which was followed by cicatrization of corresponding fistulous apertures, yet the disease made more rapid strides towards the disintegration of the tarsal bones, involving their respective joints, and amputation suggested itself as the only remedy of the malady. It was performed on the 25th May ultimo.

The specimen now exhibited fully sustains the wisdom of the proceeding. Moreover it discloses a state of disintegration totally out of keeping with the clinical character placed on record. It consists of the lower part of the femur, the entire tibia and fibula, the tarsus, and a fragment of the metatarsus. The doctor had indeed hoped and attempted the saving of the knee-joint, but finding the tibia softened and not free from disease high up, he had to include the articulation in the operation.

Although the focus of the disease was obviously limited to the lower two-thirds of the tibia, having extended downwards to the foot, nevertheless the remaining portion of the shin-bone was rough on the surface and soft in consistence; the articular cartilages were white and opaque, implying some fatty degeneration of their respective cells, there was a slight increase of synovia, and the femur exhibited in the fresh state a degree of vascularity and hyperæmia not at all foreseen.

For the better appreciation of the specimen, the bones of the leg had been divided transversely, and the lower half of the tibia and the tarsus longitudinally.

It should be mentioned, that the periosteum was by no means notably thick, but that the soft parts of the amputated extremity were very succulent from œdematous infiltration, and the muscles pale and fatty.

In viewing the tibia on its surface, there was no attempt at demarcation. The lower two-thirds consisted of new bone which overlapped above the old bone, like a shingle. At the middle the new bone was osteoporotic, obviously from caries; thereabout was an ovoid cloaca leading to the medullary cavity.

At the transverse section, the new bone surrounded the old tibia two-thirds; of the latter there is but the posterior wall covered with semifluid and homogeneous pus.

On the longitudinal section of the tibia, there were but a few isolated remnants of the old structure (sequestra); the substance was made up of osteoplastic formations. The chamber was filled with pus; no vestige was left of the medullary structure. From the chamber a few cloacæ perforate the involucrum, one of which penetrates the tibio-tarsal articulation, and has thus given rise to the affection of that and of the tarsal joints and bones. The two lower extremities of tibia and fibula were connected by copiously formed new bone-substance.

In conclusion, Dr. Bauer made the following remarks: From the character of the specimen osteo-myelitis must be inferred. The periosteum is in the main healthy, and it was thus capable of supplying the vast material that encased gradually the remnants of the vanquished portion of the tibia. Where it has suffered disintegration, it is the effect of the internal trouble of the bone.

In accepting the clinical views of Herman Demme as authority, and he is unquestionably the best informed monographist on the subject,* the symptoms in the case

* Archive of Clinical Surgery, by B. Langenbeck, Billroth, and Gurlt, vol. iii. Berlin, 1862.

did by no means justify that diagnosis. The disease was, as it were, sprung upon the patient. Neither its beginning nor its course was characterized by that *deep-seated pain and swelling* upon which that author lays so much stress. There was no epiphysal separation, nor were those ichoræmic constitutional symptoms observed to which he attaches so much diagnostic importance. The very mode in which the local abscess formed in this case gave the contradiction to Demme. The extraordinary clinical character of the case under consideration must therefore be admitted. The specimen fortunately furnishes the key to the clinical divergence of the case. There is that early perforation of the medullary cavity into the ankle-joint which allowed in a measure the escape of the matter formed inside of the bone, and this certainly accounts for the absence of pain and deep-seated swelling at the circumference of the tibia. Whatever the causes of the multilocular abscess may have been, they certainly could not have resulted from septæmia, because there was no constitutional evidence of that description.

In summing up the results of our investigation, we are led to the conclusion that the early perforation of the medullary cavity relieves the most aggravated symptoms of osteo-myelitis, and changes materially its clinical manifestations.

AMPUTATION AT THE KNEE-JOINT.

DR. POST expressed great doubt as to whether mere softening of the lower portion of the femur was an obstacle to amputation, as he had often found the bone in that condition, the result of inflammation; and without hesitation cut through it with the saw, and had never any bad results.

DR. BAUER was against amputation at the knee-joint, and always preferred to make his section above.

DR. POST remarked that the first case of amputation at the knee-joint that he had met with, was performed by an army surgeon upon a soldier who had been wounded in the Seminole War. After the operation, the patient was admitted into the N. Y. Hospital, and came under his charge. He was struck not only with the excellent stump which resulted, but was also well pleased with the breadth of surface which was left at the extremity. The patient in a short time was able to walk about without difficulty, and at one time performed a journey upon it of twenty miles with a common peg-leg. It was in fact a better stump than he had ever seen after amputation of the thigh. He stated further that Velpeau, in his discussion of the subject, had most conclusively pointed out the advantage of amputation at the knee-joint, and Dr. Markoe, in his paper upon the same operation, had shown its value. In all the cases that had come to Dr. Post's knowledge, the patient was able to bear the weight of the body directly upon the end of the stump, which it was well known was not often the case when the section was made higher up.

DR. BAUER thought that the number of operations that had been performed at the knee-joint, did not, as far as comparative statistics with reference to the femur were concerned, enable any one to arrive at a fair conclusion. The best surgical writers of the day express their views with great caution, and prefer to quote Dr. Markoe and his experience and his conclusions, rather than give their own. In this regard the opinion in favor of knee-joint amputation could hardly be considered as conclusive. In reference to statistics, there could be no better of the knee-joint than he had of the thigh; he had thirty-seven amputations in the middle and lower portions of the thigh, and had lost but one patient. He believed further, that as far as the latter operation was concerned, the statistics were improving every day, and that the old opinion relative to the danger to life the nearer the trunk was approached, was being rapidly overthrown. A certain German professor had shown this by the results in his cases, and explains the fact by asserting that he does not irritate the stumps with straps; that he allows them to swell, gives a chance for the fluid to escape; and it is by this plan of treatment alone, and nothing else, that his successes far exceeded any on record. Dr. Bauer had been so forcibly struck with this assertion, that he had ever since followed that surgeon's maxims. As bearing upon the point at issue, he would remind the members that the removal of the cartilage of incrustation was now being recommended in all amputations through the joint, as it was thought to give a better chance for the healing of the stump.

At this stage of the proceedings, DR. JACOBI moved that as there were a number of specimens awaiting presentation, and as the time was getting limited, that the discussion upon the prolific and perplexing question be for the present deferred.

INTRA-ABDOMINAL TUMORS IN FŒTUS CAUSING COMPLICATED LABOR.

DR. FINNELL next exhibited two interesting intra-abdominal tumors, which were contained in the body of an infant, and gave the following account of the peculiar influence these had upon its birth.

The mother was twenty-one years of age; had been married one year; and supposing herself eight months pregnant, was taken in labor at five o'clock in the evening. Her medical attendant remained with her during the night, and at five in the morning, the labor steadily progressing, the membranes ruptured and the waters were discharged. At eight o'clock the head was delivered, but beyond this point there was no progress. The gentleman in attendance made all reasonable force to extract the child, but could not succeed. He then sent for a friend, and after a great deal more force was expended, the child was in the same position. A third assistant was then summoned, but his efforts were alike unsuccessful, except that he succeeded in bringing down the arms; and when exhausted he raised the head and found it severed from the body. Dr. Finnell was summoned, and supposing the case to be one of hydrothorax, introduced a perforator, but only a small quantity of blood escaped; and in taking up the arms to make traction, they also were found to be separated, and had to be laid aside. The feet were then grasped, and version performed. When, however, the feet were brought down, it was found impossible to get the body out. Supposing, then, that it must be a case of ascites, the abdomen was next perforated, but no water came; and, almost in despair, the efforts at extraction were renewed, and after a good deal of hard work the body of the child was withdrawn. On introducing the hand into the uterus, for the purpose of withdrawing the placenta, another mass, oblong in shape, and somewhat larger than the closed fist, was found floating freely about.

On cutting open the body of the child, a tumor, precisely similar to the one found in the uterus, was discovered lying, with but slight attachments, in the abdominal cavity. It seemingly took its origin from the peritoneum. In the opposite side of the abdomen was a space left which corresponded in size to the tumor in the uterus. It was then evident that it had originally occupied that situation, and had, in the efforts at extraction, been squeezed outside of the child's body through the opening made by the perforator; and that, in common with its fellow found *in situ*, was the singular

cause of the difficult labor. The child was perfectly well formed every other way, and the mother was doing well.

Dr. Rogers asked if any testicles were discovered in the scrotum of the child.

Dr. Finnell was under the impression that he felt for the testicles and found them descended.

Dr. Jacobi thought they might either be supra-renal capsules or enlarged peritoneal glands.

Dr. Krackowizer thought that inasmuch as the tumors were so symmetrical, and both occupied the same position in the abdominal cavity of the child, they were the results of an enlargement of twin organs, and that it would hardly be probable that the two peritoneal glands should so evenly develop themselves.

Dr. Rogers stated that he had had the opportunity of examining the organs, and found them to be fibro-cystic tumors of the purest character; and as many of the cysts were lined with tesselated epithelium, it would seem as if the masses were nothing more than abnormally developed testes. It was on account of such an opinion that he had asked thus particularly concerning the presence of those organs in the scrotum. In answer to a question from Dr. Sands, he stated that the stroma was composed almost entirely of fibre and cell-structure.

On motion of Dr. Bibbins, a committee of three, consisting of Drs. Finnell, Krackowizer, and Rogers, were appointed to examine the growths microscopically, and report the result at the next meeting.

MITRAL DIRECT AND REGURGITANT MURMUR, AND PROBABLY TRICUSPID DIRECT MURMUR.

Dr Flint next presented a heart, for which he was indebted to Dr. George K. Smith, of Brooklyn; the patient from whom it was removed being under the observation of that gentleman for over a year. Dr. Flint was not prepared to give the details of the history, but presented the specimen merely with reference to an anatomical point, and also in reference to a point connected with physical exploration. He would say that the patient had the signs of organic disease of the heart, and finally death occurred from some intercurrent affection. The interest of the specimen centred in the existence of obstructive valvular disease at both the tricuspid and mitral orifices. There was a very considerable degree of obstruction at the latter orifice, in consequence of which it was so reduced in size as scarcely to admit the end of the finger; the curtains of the valve being thickened, but nevertheless capable of vibration. On the opposite side the nature of the lesion was much the same, and both were evidently of long standing. There were also aortic lesions.

"The first time," said Dr. F., "that the patient came under my observation was accidentally about a year ago. Then there was a loud mitral direct murmur without a mitral regurgitant. Inasmuch as the existence of this murmur is denied by some, this case would afford a very good illustration of its existence. It was so loud and distinct that I used the patient to verify its character to quite a large number of students.

"There is, however, another point which relates to the probable existence of a tricuspid direct murmur. This is a murmur, the existence of which, so far as I know, has not been distinctly made out; I do not think that its existence has been established. There is, however, no reason why we should not have such a murmur under conditions similar to those which furnish the mitral direct, viz. firmness with vibration."

"Dr. Smith, who has given considerable attention to physical signs, feels very well satisfied that both murmurs, the mitral direct and tricuspid direct, were audible; and he bases his opinion upon this fact, that the pre-systolic murmur, instead of being limited to a small area surrounding the apex, which is true of the mitral direct, had a wider area, and extended to the right border of the heart.

ABORTION CAUSED BY UTERINE DISEASE AT THE TIME OF CONCEPTION.

Dr. Jacobi exhibited the products of abortion from a lady twenty-five years of age. She had had two living children, the oldest being four years, the youngest two. Soon after the birth of the last she suffered from uterine catarrh, for which she was under treatment during last fall and winter. Up to the beginning of January she was much improved, but was not considered well. She stayed away from the office from this time because menstruation ceased, and she had become pregnant. In all probability she became so about the middle of January. She felt quite well until six or seven weeks ago, when she began to notice now and then a little bloody discharge. As I thought miscarriage was threatened I ordered her to bed for a time, and repeatedly kept her in a recumbent position on the recurrence of the discharge. Finally observing that her abdomen did not enlarge as it should, I allowed her to remain up permanently, supposing that the fœtus was dead, and that it would be in time discharged. It was voided to-day.

The specimen is interesting, first in regard to the condition of the placenta, which shows the signs of quite extensive inflammation, in the shape of fatty and fibrinous exudation. Secondly, the insertion of the cord is filamentous. This is of comparatively rare occurrence, as it is only once in 250 times in which it takes its origin in the membranes, and not in the placenta itself. The cord is unusually long, so that it surrounds the neck, and spreads over a large surface of the body. Then again it looks as if there is a knot in the cord at one point, and at several places it is surrounded with fibrine. There are moreover fibres attached to the amnion and extending to the body of the child, while upon the foot adhesions have taken place with the toes in such a way as to crowd them down in rather a curious manner. In conclusion Dr. Jacobi expressed the opinion that the inflammation of the decidua and placenta was due to the metritis existing at the time of impregnation.

Dr. Sands exhibited a specimen of extra-uterine fœtation. During the month of August he was sent for to see a lady who was supposed to be suffering from cholera. He was told that she was seized with abdominal pain on the evening previous, which was both sudden and severe, and had extended up to a short time before the visit. When seen she was almost moribund, her lips were blanched, her surface cold, and her voice was reduced almost to a whisper. She had, however, no *vomiting* or *purging*. It was ascertained that she had menstruated six weeks previously, and that for the last day or two she had had a slight discharge from the vagina. The symptoms pointed towards internal hæmorrhage. She only survived a few hours; and on post-mortem examination a fœtus was found developed in the Fallopian tube, midway between the uterus and fimbriated extremity. There were several pints of blood in the peritoneal cavity.

Adjourned.

Special Departments in King's College Hospital.—It is in contemplation to make two special departments in King's College Hospital: one for diseases of the throat, which for the present will be under the charge of Dr. George Johnson, who will give laryngoscopic demonstrations; and the other for diseases of the skin, which Dr. Duffin will superintend.

EAST RIVER MEDICAL ASSOCIATION.

STATED MEETING, JUNE 4, 1867.

DR. VERRANUS MORSE, PRESIDENT, in the Chair.

DR. W. F. THOMS, in behalf of the Delegation to the American Medical Association, presented a brief summary of the questions discussed at their last session.

SCARLATINA AND RUBEOLA—ARE THEY STRICTLY CONTAGIOUS?

A discussion relative to the late classification of scarlatina and rubeola among the contagious diseases, by the Metropolitan Board of Health, resulted in the appointment of a special committee to report at the next meeting. The committee as appointed consisted of the following:—Drs. G. V. Skiff, M. S. Buttles, W. F. Thoms, R. J. O'Sullivan, and Truman Nichols.

A CASE OF AXILLARY TUMOR.

DR. ABBOTT presented an interesting case of tumor in the axilla of a boy, which involved several doubtful points in the diagnosis.

THE UNAUTHORIZED RENEWAL OF PRESCRIPTIONS BY APOTHECARIES.

DR. O'SULLIVAN presented the evils of the above custom in forcible terms, and called for the appointment of a committee to be charged with the drafting of the resolutions, necessary to bring the matter before the parties concerned. Drs. O'Sullivan, Newman, and M. L. Smith, were constituted said committee.

A PESSARY ON A NEW PRINCIPLE.

DR. BUTTLES exhibited a pessary invented by himself, for which he claimed the possession of at least one desirable quality, that of harmlessness;—although of course, he expected to have other requisites of a more positive character. But those who had occasion to witness some of the evils resulting from even properly applied pessaries, such as the horse-shoe, or double S, would appreciate his remark.

Among these evils might be mentioned ulceration at the points of contact between the instrument and the tissues, to say nothing of the fact, that occasionally the *ascending rami* of the pubes had even been deprived of periosteum as a result of prolonged use.

He recognized the principle that the vagina was the chief support of the uterus, and that while the broad end or base of this gutta-percha pessary, now exhibited, held up the uterus, the smaller one floated in the vagina. It also possessed another advantage, that of being readily moulded to any shape by dipping in oil and passing through the flame of a spirit lamp.*

CONTINUED VOMITING AFTER THE APPARENT COMPLETE REDUCTION OF A STRANGULATED HERNIA.

DR. STEIN gave the details of a case, which had occurred in his own practice, where the vomiting continued after the hernia had been to all intents and purposes reduced. This he explained on the hypothesis that a small portion of the intestine had been inclosed between the muscular fibres of the over-lying muscle, and there was in fact virtual strangulation, although to a very limited extent. The patient, however, recovered.

DR. NICHOLS had remarked the same phenomenon once or twice n his own practice.

DR. M. L. SMITH related a case in which the protrusion had been returned "*en masse*," and an autopsy revealed the presence of membranous girdle which encircled and tightly grasped a knuckle of intestine. He regarded Dr. Stein's explanation as not only probable but correct.

The meeting then adjourned.

* A woodcut, and fuller description of this pessary, will probably appear in a subsequent number of the MEDICAL RECORD.—*Ed.*

STATED MEETING, JULY 2, 1867.

DR. VERRANUS MORSE, PRESIDENT, in the Chair.

REPORT OF THE COMMITTEE ON THE PROPHYLAXIS OF SCARLATINA AND RUBEOLA.

DR. SKIFF read the following report, which was signed by all the members of the committee, and which was subsequently adopted as the sense of the meeting:

Keeping within the province of the subject sketched out, it will answer the purpose of the committee to consider such characteristics as are common to both measles and scarlatina. In compliance with this plan, and adopting the hypothesis most generally entertained respecting the matter of contagion, and the miasm of infection, we observe:

1. Measles and scarlatina are incident to childhood, but may occur at any age.

2. That having occurred once, they constitute an immunity against an attack of the same disease.

3. That they are each caused by a miasm extraneous to the human body, and portable by means of fomites.

4. That they are not inoculable. or preventable to any extent by substituting a less fatal or a less infectious disease.

5. That they are not peculiar to any social condition of society;—the malign or non-malign characters being mostly dependent on a more or less pernicious epidemic, the peculiar condition or idiosyncrasy of the individual attacked, or the complications which may occur in the course of the disease.

6. That they are self-limiting diseases.

7. That the fatality seems to depend more on the virulence of the particular epidemic than the amount of miasmatic infection entering the system.

The committee concluded that:

1. Measles and scarlatina, though originating from causes extraneous to the body, are so commonly prevalent that they are naturally diseases of childhood,—but are nevertheless incident to any period of life. As then there is no certain exemption from these diseases, it would seem desirable for prudential reasons that they should be contracted in infancy, while the child is surrounded by parents and friends who can supply the adequate nursing and attention.

2. It is evident that if every case of measles and scarlatina could be completely isolated from the non-infected, and all healthy persons for ever unexposed to the poisonous infection, the diseases in question would become extinct. But although this is impossible, the other extreme of allowing a virulent epidemic to prevail without the opposition of the humanitarian or physician would be unreasonable, nay more, unnatural. The happy mean challenges our attention as at once practical, philosophical, and charitable.

So then since a mild form of either measles or scarlatina is a conservator as effectual as the most malignant against a second invasion in the individual, the indications are to avoid the more malignant if practicable.

3. Practically the idea may be elaborated thus:—

a. Isolation should be enforced in the case of patients suffering from any disease but ill calculated to bear any additional burden. To these may be added a sub-class of pregnant women.

b. In a serious epidemic, the infected should be isolated from those who have not yet been attacked; to this plan may be added, thorough ventilation, cleanliness, and the use of disinfectants.

In the investigation of the subject under consideration the Committee called upon Dr. Elisha Harris, Secretary of the Board of Health, and received in reply to their questions the following letter:—

OFFICE OF THE METROPOLITAN BOARD OF HEALTH,
No. 301 Mott Street, N. Y., June 5, 1867.

In reply to the questions—

1. What sanitary measures are now adopted and suggested by the Board of Health to prevent and to mitigate scarlatina, small-pox, and measles?

2. What is recommended to the physicians who have patients with these diseases? the following statements are submitted as embodying, in an unofficial form, all the facts on the subject so far as the officers of the Board have given advice or orders relating to these diseases:—

a. The persons sick with any of these diseases among the poor or ignorant classes should be kept isolated entirely from all except the members of their own families or nurses.

Generally it is expected that a person sick with small-pox or varioloid must be sent to the Small-pox Hospital on Blackwell's Island; and upon most such cases the Sanitary Superintendent issues his official order for the transfer of the sick person.

b. The sick rooms and all that pertains to them must be kept *constantly ventilated*, and the fire-place be kept open,—occasionally or constantly having a little fire in it, if there is such a fire-place.

c. Fresh chloride of lime or flasks of fluid carbolic acid are advised to be kept in the room, placed in secure position.

d. Every article of personal clothing and bedding that has been in contact with the sick person should be placed in boiling water or in a solution of some positive disinfectant—such as solut. permang. potassa (4 3 to 2 or 3 galls.) or one of the chlorine solutions. The same dilute solutions of the disinfectants should be sprinkled about the rooms where the sick lie, or, what is better, they may be evaporated from wet cloths suspended. This practice is recommended where there is an epidemic in a crowded population.

e. The cleansing of the houses and premises where any such infectious disease has prevailed is also important. Whitewashing with fresh-slaked lime or with chloride of lime; scrubbing floors and all woodwork and hard walls with hot solutions of chloride of lime; and the keeping of windows and doors open for several days, are the chief measures.

This practice is now applied to diphtheria, typhus, typhoid, "spotted fever," and cholera; but the few cases of spotted fever hitherto seen are not supposed to have been infectious; they were surrounded by localizing sources of disease.

(Signed) E. HARRIS,
Cor. Secretary of Metropolitan Board of Health.

In conclusion, the Committee would make the following practical suggestions:

1st. That during an ordinary epidemic of measles or scarlatina, no sanitary measures, except ventilation and cleanliness, should be employed.

2d. That during a severe epidemic of these diseases the following sanitary measures should be adopted.

A. *Isolation.* The patient should be placed in a room apart from the rest of the family and attended by a person who has had the disease—no communication being allowed with the rest of the family.

B. *Ventilation* and *Cleanliness.* The windows of the room should be kept constantly open, and whenever practicable a fire in a fire-place, with a view to add to these means, should be constantly maintained.

The most thorough cleanliness should be insisted upon —and bed-linen ought to be changed as often as practicable.

C. *Disinfection.* Every article of personal clothing and bedding once in contact with the patient should be steeped in boiling water or in a solution of the permanganate of potassa (1 oz. of the permanganate to three gallons of water).

The chamber vessels should be disinfected by a solution of sulphate of iron and carbolic acid.

D. *Fumigation.* After patients have recovered, the room in which they were sick should be vacated for at least twelve hours,—every window and aperture closed, and upon an iron pipkin or kettle with legs burn a few ounces of sulphur.

Let the room be kept closed for eight hours and then ventilate thoroughly.

PRESCRIPTIONS THE PROPERTY OF THE PRESCRIBING PHYSICIAN.

DR. O'SULLIVAN, as chairman of the committee upon the Grievances of Practitioners and their right to prevent the unauthorized repetition of their prescriptions, reported that as far as interviews with apothecaries had been obtained the latter fully agree with the committee that the proposed action of the Association is necessary and of great importance. Many of these pharmaceutists indeed expressed themselves surprised that the profession did not move in this matter at an earlier date, thereby relieving them of great responsibility, and placing the control of this matter more directly in the hands of the profession. A few did not refuse to accede, but from their answers it was evident they would be governed by the action to be taken by the physicians in the matter. The committee hoped that the resolutions about to be presented were sufficient and explicit enough to meet these objections They further had the pleasure to report, that the members of the profession addressed on the subject approved the movement and thought that it would become general, not only in this, but in other cities of this State and country. They say, further, that it is understood the Academy of Medicine and other societies of this city will move in this matter immediately.

The resolutions were then adopted and are as follows:

Whereas, The attention of this Society has been called to consider the propriety of taking action relative to the practice of druggists renewing the prescriptions of physicians without their written order, thereby injuring very materially the pecuniary interests of the profession, without gaining any particular benefit to themselves; and

Whereas, In view of the graver and more important consideration that the interests and lives of patients are, in consequence, endangered, we consider it a duty to guard to the utmost of our ability against the liability to mistakes which should be prevented rather than deplored; be it therefore

Resolved, That we cordially invite the earnest coöperation of every druggist in this city, especially in our immediate districts, to further this laudable purpose; and be it further

Resolved, That we respectfully request that no druggist will renew the prescriptions of any physician connected with this Society, without due authority for each and every such renewal. Further, we will regard as unworthy of our patronage any druggist who fails to comply with the requirements of these resolutions.

Resolved, That a copy of these resolutions, with a blank card, be sent to each and every druggist in our districts, with a request that the card be returned within two weeks to the Secretary, signifying their intentions, with

reference to compliance, or non-compliance, with these resolutions.

The Association then adjourned.

Correspondence.

THE UTERINE ELEMENT IN PRACTICE.

To the Editor of the Medical Record.

Sir—I cannot withhold my approbation of your article on this subject in your number for July 1. Such plain talk is eminently necessary at the present time, for the uterus has come to be the arena for the most crying abuse that exists in our profession. There is both more ultraism and more quackery exhibited by respectable medical men in connexion with this organ than any other part of the system. The speculum has become as common in some quarters as the stethoscope, and many women talk as freely about diseases of the womb as they do about those of the stomach or lungs. Thirty years ago Dr. Balbirnie, a Scotch physician, held this language of the speculum: "We go forth its advocate; we proclaim ourselves *the apostles of the speculum.* With that instrument we link our fate, and by that we will stand or fall." How the apostles of this instrument have multiplied since then! They are in every city, and in multitudes of towns, and even villages. This apostleship is the best stock in trade of many a rising doctor.

Far be it from me to decry the speculum and other kindred uterine instruments; but I honestly believe that on the whole they are used ten times as often as they ought to be. Indeed, some who intend to use the speculum within proper limitations are obliged to employ it more than they wish to, because the influence of other physicians is so strong for it. This is true of myself. It occurs in this way: A patient presents herself who has formerly been under the care of one of those aforesaid apostles. She is terribly familiar with the speculum, and with all the technical as well as common language about the uterus, for these apostles are wonderfully instructive to their patients. She imagines that she has an ulcer on the mouth of the uterus; and though I not only see no evidence of this, but positive evidence to the contrary, I am forced to use the speculum in order to satisfy her that I am correct in my diagnosis. Sometimes the influence is less direct, but none the less powerful, at least in some of the cases. What the patient has heard from her friends Mrs. A and Mrs. B, who have been under the touch of those apostles, may have so convinced her that she has disease of the womb, and that it must be *looked into*, that the speculum must be introduced, or the patient will pass into other hands.

There are fashions in disease as well as in modes of practice. Certain diseases prevail at certain periods, not because they are really more abundant then than at other times, but because there are abounding thoughts about them, both in the medical and in the public mind. When Corvisart published his book on diseases of the heart, those diseases were at once very prevalent. At one time dyspepsia was the most common word on the tongues of invalids; at another, throat diseases were in the fashion, and tonsils were clipped and throats swabbed; at another, spinal complaints were all the rage; but now female diseases are in the ascendency. Womb on the brain is a very common disorder, and a hard one to treat. I have seen many patients who could have been cured much quicker than they were, if all knowledge of the existence of such an organ as the uterus could have been blotted out of their minds.

The medical profession is ever running into extremes, and these extremes always furnish material for the success of routinists, and those who are ever ready to take advantage of the credulity of the public. There are some who are always found on the topmost wave of public opinion and feeling. They identify themselves as much as they can with whatever most attracts the attention of the many. They of course have seen many cases of every disease that occasions conversation and inquiry, and are ready to communicate what they assume to know on the subject.

Such men are apt at the present time to make much of female diseases. It is the easiest thing in the world to foist up a reputation for skill in them. A hint dropped here and there, some occasional wise saws about the modern advances in the appliances of our art, and the importance of thorough investigation, and the use of the speculum in all cases where there can be any plausible reason given for its use—such means can create a reputation even in spite of consummate ignorance, especially if there be coupled with it a goodly share of cunning, as there often is.

There is great temptation to aspire after such a reputation, in the fact that the favor of the women is one of the best means of obtaining a general practice. Hence it is that so many, even of young practitioners, adopt female diseases as their specialty, to be plied as the chief means of gaining both general notoriety and an introduction into families. I have known this expedient to succeed, even in the case of young men at the very outset of their practice.

A word or two as to the frequency with which diseases of the uterus occur. One would think from the representations of some physicians, that the womb of almost every woman is more or less out of place. Some of us that have been in practice a good while have certainly had a small experience in this respect compared with that which some rather recently-fledged ones claim to have had. If we are wrong, if many of our patients have really had flexions and displacements of the uterus, and we have not known it, the inference is a pretty clear one that such difficulties can exist without doing much harm. This we do not believe, and so we infer that the alleged difficulties do not exist anything like as often as some suppose. A case now and then occurs which throws some light on this point. I give a single one:—A lady had been under my care for a difficulty which was manifestly essentially nervous, and was gradually recovering, though not with uniform progress; for such cases, above all others, are liable to occasional relapses. In one of these relapses she passed into the care of one who was famous for having many cases of uterine misplacements. He pronounced her difficulty to be mainly anteversion of the uterus, which I knew was not so. I speak positively on this point, because I had shortly before made an examination which would have revealed this misplacement if it had existed. The result showed that I was right. If there was such a displacement, a rapid recovery, as was promised, should surely have followed the adjustment of the organ. But instead of this there was the same gradual but irregular recovery that had been going on while she was under my care. The question here arises whether there is not some hazard in making such promises of rapid recovery in such cases. Not much; for the patient may be somewhat benefited by the cordial influence of the new hope, imagination helping on the change; and if the recovery be as slow as before, this may be plausibly attributed to the length of time that she had suffered from the misplacement. Or it may be pretended that there are occasional partial returns of the

dislocation requiring a new adjustment, and that this of course retards the recovery.

There are some other points, as ulceration of the os uteri, that I intended to touch, but this article is already sufficiently long, and I leave those for your next number. *

ANTERIOR LUXATION OF THE CARPAL EXTREMITY OF THE ULNA.

To the Editor of the Medical Record.

Dear Sir—I communicate the following history of a very rare accident, in order that you may place it where it may be of service to the profession.

Kate ——, an Irish domestic, of about twenty years of age, and rather slender form, presented herself at the Demilt Dispensary on the 19th of June, 1867, and gave the following account of her accident. On or about the 1st of the month, while wringing clothes, she suddenly felt her wrist give way, experienced considerable pain in it, and noticed that she could not move it, nor rotate the forearm. Regarding it as a wrench of the joint, various domestic prescriptions were employed, during a period of some days, with unsatisfactory results. By the advice of friends she then applied to the "Institution for the Ruptured and Crippled." The character of her injury was there recognised, and diagnosed as "Spontaneous dislocation of the lower extremity of the ulna."

Rest upon a splint prescribed. Not satisfied with her progress towards recovery, the patient, after waiting many days, finally came to the Dispensary, as above stated, still carrying her wrist upon the splint. The limb presented the following deformity. Forearm fixed in a supine position; the wrist almost immovably fixed in the position of moderate extension; and the fingers moderately flexed and much stiffened. The styloid eminence of the ulna was altogether absent, the wrist on its posterior aspect sloping downwards and inwards towards the ulnar border of the limb. On the palmar aspect of the wrist the head of the ulna was distinctly recognisable, filling up the natural depression immediately behind the pisiform bone, and even rising above its level. The exact position of the bones of the forearm in this deformity I believe to be, *the resting of the internal palmar border of the sigmoid cavity of the radius, in the depression on the dorsal surface of the ulna*, between the styloid process, and its head, the depression forming the groove for the tendon of the extensor carpi ulnaris muscle. This, as a reference to the skeleton will show, produces a palmar displacement of the carpal end of the ulna of half to three-fourths of an inch. It results in the rupture of the anterior radio-ulnar ligament, inevitably, and perhaps of the corresponding posterior ligament. The inter-articular fibro-cartilage is, in all probability, also torn at its attachments or in its continuity. This position also results in putting upon the stretch the tendon of the extensor carpi ulnaris; portions of anterior carpal ligament, and the internal lateral ligament, as well as the interosseous ligament. I believe the obstacle to reduction is mostly to be found in this last ligament. I do not regard the pronator quadratus as involved in this accident, it being no doubt in a state of relaxation. With this view of the anatomy of the luxation, its reduction was easily accomplished by first steadily extending the hand and then flexing it laterally towards the radial border, thus creating a fulcrum of the radio-carpal surface by which to employ the chain of carpal bones as a lever to raise the ulna from the radius through the internal lateral ligament, the medium of attachment of the weight or resistance: and secondly, by a grasping antero-posterior pressure, effected by placing the fingers upon the palmar aspect of the lower end of the ulna, and the thumb of the same hand upon the dorsal surface of the corresponding portion of the radius. This combined force of extension and pressure promptly restored the bones to their normal position, but without snapping, sudden slipping, or other usual phenomena of the return of dislocated bones to articular cavities. It is also more than probable that this process of extension had the additional value of extricating the styloid prominence of the ulna from the carpal bones and ligaments, for they are undoubtedly more or less approximated by the tension of the ligaments and tendons already enumerated. Mobility of the forearm and wrist was at once restored, and the joint presented the same conformation as the opposite one. No experiments were practised with the view of testing the tendency to a reproduction of the dislocation. The forearm and hand were laid in the prone position upon a board, a cushioned roller placed under the wrist between it and the board for the purpose of maintaining a semiflexed position of that joint, and the whole secured by a bandage. Four days later this dressing was removed, and free but gentle movements of the wrist and forearm recommended and practised. There was at this time no manifest tendency to redislocation. Some six days later the movements of the wrist were perfectly free and painless, but there was considerable tenderness over the radio ulnar joint, some swelling, and the movements of pronation and supination were executed slowly and with much discomfort.

Prognosis, slow recovery of this movement.

No manifest tendency to redislocate.

I do not presume that this history, or the remarks in connexion with it, will present anything peculiar or instructive to all of your readers, but as a rare accident, it appears to me to merit a record.

The prolonged presence of the bones out of their normal position in this case—a week or ten days longer than there was any excuse for their remaining—had doubtless much to do in the production of the subsequent protracted tenderness of the radio-ulnar articulation and of the unfavorable prognosis.

Truly yours,

Stephen Rogers.

A NEW SYRINGE FOR THE EAR.

To the Editor of the Medical Record.

Dear Sir—In your issue of June 15, "How to syringe the ear" reminded me of an ingenious apparatus for this purpose, contrived by Surgeon W. S. W. Ruschenberger, U. S. N., and exhibited to me in 1862 at the Navy Yard, Boston.

Never having seen such an arrangement elsewhere, and presuming the doctor's well known modesty prevented him from giving publicity to so simple a thing, I pick it up as a crumb which seems to me to be worth saving.

It consisted of a tin quart cup divided into two equal compartments by a septum of tin, from top to bottom. In the compartment next the handle of the cup was fixed perpendicularly a proper syringe with a pipe leading up and across the top of the cup. The end of the pipe, near the nozzle, was made flexible for a short distance, for convenience of direction. When an ear was to be washed out, the doctor filled the syringe compartment with pure water, or other injection, placed the edge of the front compartment against the neck, and proceeded to inject. The regurgitating fluid, together with the morbid secretions of the ear, flowed into the

front compartment without communicating with the syringe, thus giving him the advantage of repeated clean injections.

Wm. J. Burge, M. D.

Atchison, Kansas.

Medical Items and News.

Death of Civiale.—Civiale has just terminated his long and useful career. The merit of this specialist is universally conceded. His discovery of lithotrity, and his excellent treatise on diseases of the urinary organs, are titles to scientific distinction. He has always been, however, a popular subject of raillery with some of the Paris doctors; and those who accorded to him an incontestable excellence as a patient and skilful manipulator of the bougie, failed to express a respectful regard for his intellectual capacity. We shall not attempt to discuss the causes of this feeling; either that Civiale attempted to encroach too much with his specialty on the domain of general surgery, or that he was not properly appreciated. A correspondent of the *Gazette Medicale*, who judges him with severity, refuses to acknowledge that he had either grace, eloquence, or wit; the same gentleman, however, informs us that he possessed a high order of financial ability in the practice of his specialty, by which he accumulated five millions of francs. Those who do not esteem Civiale for this species of talent, let them throw the mantle of professional charity over his mental infirmities, and recollect only the good that he has accomplished in his special department.

Death of Trousseau and Follin.—The Faculty of Paris has again to mourn a serious loss in the death of two of its distinguished members: Follin, the accomplished surgeon, and the principal editor of the "Arch. Gén. de Médecine," has been cut down in middle life:—Trousseau, the eminent physician, learned professor, the fluent and eloquent orator, has recently died from cancer of the stomach. Follin belonged to the trio designated at one time with a slight irony the "jeune école;" Broca and Verneuil remain. Eminently practical, possessed of an excellent judgment, a vast erudition, and indefatigable in his zeal and efforts to advance the progress of medical science, Follin always evinced a just appreciation of the labors of his own countrymen, and regarded with justice and fitting discrimination the valuable accessions to surgery in other countries. He was the first to introduce the ophthalmoscope into France, to improve it, and to extend its use. He was one of the first to encourage the American operative method for vesico-vaginal fistula. At the request of M. Robert, Dr. Bozeman, of this country, operated successfully for vesico-vaginal fistula at the Hôtel Dieu of Paris, using his button suture; a few months later Follin practised this method successfully, and in two or three published articles discussed its value. The subject of resections, the much-controverted question of syphilis, and many other topics, received a large share of his attention. The soundness of his judgment and the vastness of his accurate knowledge, made the "Arch. Gén. de Médecine" an arbiter of the eventful questions which at different times engaged the attention of the medical public in France. He was the embodiment of successful merit, and an example of energy and application. The vigor and freshness of his intellect elicited from M. Verneuil the beautifully-expressed sentiment which compared him to a tree bearing on the same branches the flowers of youth and the fruit of mature age.

Trousseau was born in 1801, and died on the 23d of last June, at the age of 66. As the pupil of Bretonneau he commenced his medical career, which was long, active, and useful, and the medical profession sincerely laments in its loss of him one of its most valuable members. He was extremely interesting as a professor of materia medica, and impressive as a clinical lecturer. His impressive, chaste, and elegant diction, charmed and fixed the attention of his auditors, equally with the clearness of his thoughts. His manner was cordial and sympathetic. His popularity and his eloquence caused him at one time to enter the arena of political life, and he was elected to a place in the deliberative council of his nation by a majority of 25,000 votes from the "Département de l'Eure-et-Loire."

He published many memoirs and articles in the medical periodicals of the day, especially the "Archives," "Jour. des Con. Medico-Chirurg.," and the "Union Médicale"; and his work on Materia Medica is justly esteemed in France as an excellent treatise. He has also written a large and valuable work on clinical medicine. Some of the French daily journals relate a few interesting incidents to show the serenity and stoicism with which he regarded the approach of death. He pointed out to his most intimate medical friends and favorite pupils the different symptoms and physical signs of his disease, commenting upon the progressive development of the gastric tumor from day to day preceding his death, with the same precision and impressiveness that characterized his clinical lectures in the wards of his hospital.

Previous to his death he addressed a short and affectionate letter to the President of the Academy of Medicine of which he was a prominent member, requesting that no discourse should be pronounced at his funeral.

American Pharmaceutical Association.—The Fifteenth Annual Meeting of the American Pharmaceutical Association will be held in this city, commencing at 3 o'clock P. M., on the second Tuesday in September (10), 1867.

Heart Diseases in California.—An extraordinary prevalence of diseases of the heart and arteries is reported in California, owing, it is thought by the physicians in that locality, to the habit of using such large quantities of intoxicating liquors.

Treatment of Typhus Fever by Tea.—Dr. T. W. Grimshaw, of Dublin, relates 33 cases of typhus fever, of which number 21 were successfully treated by tea, without any other internal remedy of importance; and some of them were of a severe character.—*Medical News.*

ANEURISM OF THE ARCH OF THE AORTA AND INNOMMINATE ARTERY.

OCCLUSION OF THE MOUTHS OF THE RIGHT SUBCLAVIAN AND BOTH COMMON CAROTID ARTERIES; BRAIN DIRECTLY SUPPLIED ONLY THROUGH THE LEFT VERTEBRAL ARTERY.

By J. C. HUTCHISON, M.D.,

OF BROOKLYN, N. Y.

Richard Murphy, an Irish laborer, 48 years old, was found lying in the street, suffering from dyspnœa and partial insensibility, on 12th December, 1866, and was at once conveyed to the Brooklyn City Hospital. On the following day he stated that he was perfectly well until five months ago, when he began to experience "shortness of breath" after exertion, and about the same time he noticed a swelling at the right sterno-clavicular articulation. The tumor gradually increased in size, accompanied by a proportionate increase in the frequency and severity of the paroxysms of dyspnœa, which has incapacitated him for work for the past two months. He has some cough, and complains of dysphagia; but his general health is remarkably good. Pulsation in the tumor is marked, accompanied by the aneurismal bruit; pulsation in the right carotid and axillary arteries very feeble; no pulsation in the radical artery, and he complains of severe pain and numbness in the forearm and hand, along the course of the nerves.

Dr. Daniel Kissam, during whose service the patient was admitted, recognised aneurism of the arteria innominata, and Valsalva's treatment for internal aneurism was adopted, viz. rest in the recumbent posture, diminished diet, occasional abstraction of blood from the arm, and locally from the vicinity of the tumor, together with 15 drops tinct. digitalis three times a day. This treatment was continued for a month without apparent benefit; indeed the paroxysms of dyspnœa had increased so as to threaten a fatal termination at any moment.

At a consultation of the surgeons of the Hospital, held on the 10th January, 1867, it was decided to ligate the arteries on the distal side of the aneurism, as suggested by Brasdor.

Jan. 13th.—Last night he had three severe paroxysms of dyspnœa, during which his surface became livid and cold, eyes fixed, pupils dilated; violent convulsions also occurred, after which he remained for some time unconscious.

On the 16th January, with the concurrence and assistance of my colleagues of the surgical staff, I determined to ligate the right common carotid and subclavian arteries. An incision was made, commencing at the upper border of the sternum in the mesial line, and extending outwards, just above the clavicle, for three inches; another incision of the same length extended along the outer margin of the sterno-mastoid muscle, and joined the first at the top of the sternum. The integuments, the platysma, the cervical fascia, and both origins of the sterno-mastoid, were divided in succession, and turned outwards; the sterno-hyoid and sterno-thyroid were drawn inwards without being divided; the sheath containing the common carotid was now exposed and opened, and a ligature was applied to the vessel about an inch above its origin. I then followed the carotid towards its origin for the purpose of reaching the subclavian at its first part; but failing to find this portion of the vessel, I passed the finger along the margin of the scalenus anticus down to the first rib, exposed the vessel there, and applied a ligature on the outside of the scaleni muscles. The brachial plexus was exposed, and care was taken to prevent the aneurismal needle from engaging any of its branches. There was no distinct pulsation in the subclavian artery. Not more than two ounces of blood was lost during the operation. The wound was closed by the interrupted suture, and dressed with cold water, and an anodyne was administered.

January 17th.—Patient has had a more comfortable night than for several weeks before; wound united throughout nearly its whole extent; two sutures removed; he moves his head in all directions with as much facility as if his right sterno-mastoid had not been divided. Stimulants were freely given with full diet.

January 28th.—Ligature on the carotid came away to-day; he breathes quietly and has been very comfortable in all respects since the operation, with the exception of the continuation of the pain and numbness in the right arm and hand which he had for a long time before the operation.

Feb. 7th.—The nurse states that while dressing the wound this morning he removed the subclavian ligature, which was lying detached upon the surface of the wound, and threw it away; patient very comfortable.

Feb. 25th.—Since the last record the patient has had slight erysipelas of the right side of neck and face, and for two or three days has suffered from occasional paroxysms of dyspnœa similar to those which he had before the operation, but less severe.

He died from suffocation on the 26th February, 41 days after the operation.

Post-mortem, 24 hours after death. A careful dissection of the neck was made by Dr. Speir, Curator, and one of the physicians of the hospital, in the presence of Drs. H. S. Smith, Bell, Landon, and myself. The specimen showed aneurism of the arch of the aorta and innominate artery, involving the origins of the right subclavian and common carotid; the two latter vessels being separated where they pass off from the tumor, about one inch. The aneurismal sac was nearly filled with concentric layers of fibrine; the orifices of the right subclavian, right and left common carotids, were firmly closed by clot, the left subclavian being the only vessel arising from the arch of the aorta through which the blood could be transmitted. The clot in the right subclavian extended to the distal side of the vertebral artery; that in the right common carotid to the point at which the artery was cut through by the ligature, one inch above its origin, and from thence to the bifurcation into internal and external carotid. The right subclavian was pervious at and beyond the point to which I had supposed the ligature was applied, and the coats of the vessel exhibited no evidence of having been ligated. The brachial plexus of nerves and the omo-hyoid muscle were carefully examined, and found to be in a normal condition. The trachea was very much compressed by the tumor, and this was the immediate cause of death. The left vena innominata was obliterated. The left vertebral artery not enlarged.

Remarks.—The above case presents several points of interest. First.—The brain received its direct supply of blood only through the left vertebral artery, all the vessels going off from the arch of the aorta, except the left subclavian, being firmly occluded for a long time before death, judging from the appearance of the clots they contained. Notwithstanding this, the brain did not appear to suffer from a want of a due supply of blood; his intelligence was perfect to the last moments of his life.

Second.—The right arm, both before and after the operation, had the same temperature, judging from the sense of touch, and was as well nourished as the left. The blood must have reached it through the anastomosis of the right superior intercostal with the aortic intercostals, the anastomosis of the inferior thyroids, as well as the right internal mammary and epigastric.

Third.—To what was the second ligature applied? I am disposed to regard the suggestion made by my friend, Dr. Krackowizer, that it was applied to the *sheath* of the vessel, as the sheath was unfortunately not examined at the post-mortem,—most probable. The subclavian was situated at an unusual depth, and it did not pulsate decidedly where it was exposed, although pulsation was observed in the axillary before the operation. Every surgeon knows that the pulsation of an artery is much more distinct before it is uncovered than afterwards. Repeated examinations, made with the greatest care by myself and the House Surgeon, Dr. Shephard, failed to detect pulsation in the axillary artery after the operation. The pressure made by the displacement of the parts around the vessel appears to have been sufficient to arrest its pulsations.

The relief which the patient experienced after the operation, continuing until a few days before his death, was owing to the division of the cervical fascia and muscles, which permitted the tumor to recede from the trachea.

A CASE OF AMPUTATION AT THE HIP-JOINT FOR GUNSHOT WOUND OF THE HEAD OF THE FEMUR.

By H. A. DUBOIS, M.D.,

ASSISTANT SURGEON AND CAPTAIN U. S. ARMY.

Antonio Mutieries, a Mexican, aged about 33, employed by the Quartermaster's department as a teamster, was received into hospital, May 11, 1867. Early that morning he had had a difficulty with another Mexican employed in the same train, which resulted in his drawing a pistol upon his opponent, who instantly drew and fired his revolver at him, the ball taking effect in his left hip. I saw the case soon after his admittance, at about 11 A.M., and found the wound of entrance about two inches beneath and a little in front of the anterior superior spinous process of the ilium. He was suffering little, and there was little or no hæmorrhage. I enlarged the wound, introduced my finger, and traced the ball to the neck of the femur, where it was firmly lodged at the point where it joined the head of the bone. With a Tiemann's forceps I with some trouble removed the ball and a small piece of wadding. It was an ordinary conical revolver ball, and was fired at a distance not exceeding two to three yards. The man was kept perfectly quiet, a cold-water dressing applied, and he was fed with easily digested and nourishing food. At this time, and for the period of some two weeks, there was no inflammation involving the joint—a smart blow on the heel causing no pain.

The patient gradually lost flesh, but suffered little. The discharge from the wound consisted, for the most part, of ill-formed pus, having little smell, and occasionally streaked with blood. A few small pieces of bone were subsequently exfoliated. The patient slept little, and perspired much at night; his appetite also diminished, and he was evidently losing strength daily. In addition to the above symptoms, the following were afterwards superadded: Internal pain running up the side and down the thigh to the ankle, much aggravated by the slightest movement, or by the least pressure on the heel. These symptoms increasing, I proposed the operation afterwards performed, but could not gain his consent thereto, he informing my interpreter that he would be up and on his crutches in two weeks. I had previous to this made up my mind as to the propriety of amputating at the hip, and felt confident of ultimately obtaining the patient's consent, as a relief from the terrible pain suffered in these cases. I had rejected the operation of excision, as, in the only case in which I had performed it, it had caused a shock as great to the system as I believed would result from amputation; and though I found any number of authors who recommended excision in preference to amputation in this class of cases, I found also that they had, with few exceptions, never tried or seen it tried in cases resulting from gunshot injuries. Of the thirty-two cases in which excision was performed during the late war, four only were successful, and how far they succeeded in giving a useful limb is not fully recorded.

Surgeon J. C. McKee, U. S. A., visiting the post at this time, I asked him to examine the case, which he did, and advised amputation in preference to excision. Some ten days after I first proposed the operation, I obtained the patient's consent, and as I deemed it advisable, owing to the rapid loss of strength, that the operation should be performed as early as possible, I at once made my arrangements; and on the 22d of June, having obtained the assistance of Doctor Shout, of Los Vegas, Doctor Simpson, of Moro, and Hospital Steward Enfield, U. S. Army, I proceeded at 12.30 A.M. to amputate. I had had previously constructed by a blacksmith a rough clamp for compressing the aorta. The patient was quickly put under the influence of a mixture of ether and chloroform, removed to the operating-table, and all of my assistants having previously been informed of their duties, the operation was quickly and readily performed—the thigh being removed in, I am told, about fifteen seconds. The clamp controlled the arterial hæmorrhage well, in fact so well that it was extremely difficult to find out and secure the arteries; but the venous hæmorrhage was more troublesome. Some fifteen ligatures were used in all. Little blood was lost, however. The acetabulum was found much necrosed, and the tissues a good deal diseased. The diseased bone and tissues, as far as practicable, were removed, and a cerate cloth laid between the flaps, and the patient was then put to bed.

His condition during the operation was, on the whole, good, the pulse several times becoming extremely feeble, but it quickly rose again under slight stimulation. The breathing was free. The clamp, which made pressure one inch above and to the left side of the umbilicus, apparently caused no inconvenience, and certainly interfered little, if any, with his regular breathing.

The anterior flap was made long, while the posterior was made extremely short. The patient, before taking the anæsthetic, received hypodermically one-half grain of morphiæ sulph., and on recovering from their joint influence he said he felt no pain, talked, and seemed at perfect ease. He was given small quantities of brandy and beef-tea, also a little ammonia, as the pulse was feeble and rapid. He complained of great thirst, and craved ice, which was given him in small quantities. I hoped by these means to bring about reaction, and to overcome the profound shock under which his system was laboring. His pulse gradually became more feeble, ran up to 160 and 180, and became imperceptible; and yet he was lively, talked much, and was in every way perfectly sensible. He complained of hunger, said he was "as hungry as a dog," and rejected almost immediately everything he took into his stomach. In this

condition I resorted to hypodermic injections of tinct· opii, with the effect of bringing up the pulse, and quieting to some extent the irritability of the stomach. In this state he lingered about thirty hours, sometimes almost or entirely pulseless, but with a warm skin, and perspiring profusely; at other times with a quick, feeble pulse, sleeping a few moments at a time, until half past five on the evening of the day after the operation, when, taking a piece of ice in his mouth, he said, "I am going," and died almost immediately.

A post-mortem showed the flaps glazed to some extent, but not united. The acetabulum and head of the femur were both extensively necrosed, and the tissues much diseased. Wire sutures, it should be added, were used to close the wound, which was done some ten hours after the operation.

If the operation did not save the life, it at least promoted the happy dying (euthanasia), which Hippocrates says the physician should have as his second object—considering the saving of life his first.

FORT UNION, NEW MEXICO.

SYPHILITIC AFFECTIONS OF THE CONJUNCTIVA.

TRANSLATED FROM THE FRENCH OF M. LE DOCTEUR DESMARRES, PROFESSEUR DE CLINIQUE OPHTHALMIQUE, CHEVALIER DE LA LEGION D'HONNEUR, ETC.,

BY WM. MASON TURNER, M.D.

PHILADELPHIA.

CHANCRE.

WE have already, in our first volume, studied the syphilitic affections of one of the constituent parts of the visional apparatus (*Affections syphilitiques des paupières*, p. 620). Perhaps it will not be inopportune here to refer to a case, in which the chief symptoms of chancre, of undoubted genuineness, were found on the conjunctiva. This case has this curious point connected with it, that not only has the ulcer shown every characteristic of the primitive specific affection, but that it has been early considered as cause of a *foreseen constitutional affection*. Indeed for the one part, it was deep, its borders were perpendicular, the bottom was covered with the grayish, pultaceous matter, only found in primitive syphilitic ulcerations; and on the other hand, the indolent engorgement of the neighboring lymphatic glands (indolent non-suppurative adenitis) indicated clearly, after all, a small glimmering of the constitutional affection, which would soon show itself by pathognomonic phenomena, and which would demand an appropriate constitutional treatment.

Facts of this species being sufficiently rare, we will report *in extenso* this experience, the details of which are sufficiently complete, sufficiently retrenched, to enable us to dispense with tracing a general history of chancre of the conjunctiva.

CASE I.—On the 31st July, 1854, Madame M., embroiderer, aged thirty-four years, presented herself at my clinic.

In the large angle of the left eye, in the depression at the internal extremity of the upper eyelid, there was a tumor of the size of three hemp-seeds, presenting the form and appearance of an inflamed follicle. The swelling in the neighboring parts was very considerable; the tissues were of a vivid red; the central part of the tumor was much more prominent than the circumference. The portion of the conjunctiva which surrounded and completed the *cul-de-sac*, was likewise very red; the carunculus was tumefied, and the eye constantly wet with tears. Touch of considerable pressure produced no pain. The patient could give no satisfactory account of the affection. Believing it to be nothing more than an inflamed follicle, accompanied by an intense conjunctivitis, I was induced to prescribe a collyrium of the subacetate of lead for fomentations, and cataplasms made of the ashes of lettuce leaves, to be placed over the left eye at night.

On the 4th of August, the patient returned to the clinic. The most salient part of the tumor had ulcerated. The loss of substance, of about one *centimètre* in size, measured nearly the entire diameter of the tumor which has been described. Its aspect was characteristic; the borders were abrupt and perpendicular; the bottom was covered with a yellowish-gray matter, precisely similar to that which we see in primitive syphilitic ulcerations. At the same time I determined a manifest engorgement of the lymphatic pre-auricular and submaxillary glands, painless and accompanied with no change of color in the dermis. Of course, I was no longer in doubt, and for my first diagnosis I unhesitatingly substituted this: *specific* ulceration of the conjunctiva. Inflammatory symptoms being very marked, I directed the continuation of the emollients, and prescribed in addition, wherewith to bathe the eye seven or eight times a day, the following collyrium:

℞. Aquæ destil. 100 gram
Hydr. chlor. corros. 0.05.
M.

and directed the patient to take a Sédillot pill, night and morning. (This pill is sometimes called the *saponaceous mercurial pill*, and is as follows: unguent mercur. (equal parts) 12 gram., sapo. medicat. 8 gram., pulv. glycyrrh. 4 gram., M; ft. pil. of 20 centigrammes each. Each pill contains five centigrammes of mercury.—*Translator.*)

On the 7th, the ulcer was in the same condition. The gums were swollen a little and showed signs of commencing stomatitis mercurialis. The pills were discontinued; gargles of water, and vinegar of squills, with sarsaparilla as a drink, were ordered. On the 9th I examined the patient in consultation with M. le docteur Clerc, who recognised at once, with me, the apparent characteristics of chancre in the ulcer, but did not venture to affirm anything definitely as to the nature of the affection, without a new examination, to be repeated after some days; he advised solely a purely expectant treatment. Emollient fomentations, and a collyrium of borax, were ordered.

On the 24th of August, my honorable *confrère* sent me the patient with this note: "There is nothing to suspect from the appearance of the genital organs; the persistence of the auricular adenitis, and the adenitis of the walls of the mouth, creates a presumption of a constitutional infection, which, in a word, will not be well before a month." Finally, on the 21st September, Madame M. returned to see me, with this diagnosis from Doctor Clerc: *Papular lenticular syphilide.* The mercurial stomatitis, having been cured for over three weeks, the patient was subjected to a treatment by the prot-iodide of mercury.

On the 29th of the same month, the ulceration of the conjunctiva had completely cicatrised. The papulous syphilide diminished rapidly, and the auricular ganglion was in the way of improvement. It is needless to say that the most pressing questions addressed to the patient, failed to produce a satisfactory response as to the *origin* of the complaint.

In our first article on syphilitic ulcers of the eyelids, we noted a fact of the same nature as the preceding, observed by us in a midwife (*sage-femme*), and whom we sent to our *confrère*, M. le docteur Pajot, *Professeur*

agrégé d'accouchements to the Faculty of Medicine of Paris.

Below I append a little history of this other case, which one cannot, without some interest, compare with that which has been given.

Case II.—Madame G., *sage-femme*, aged thirty years, of a lymphatic constitution, of good general health, very regular, and never, as she assured us, had been sick at all. She was not subject to rheumatism, and showed no traces of engorged or suppurative glands. She presented herself at the clinic, for the first time, on the 2d of February, 1852. Her left eye had been ailing for fifteen days. The inferior palpebral conjunctiva had been much swollen during this time. There had been no pain, and none existed at the time she came to the clinic. In the middle of the conjunctiva, in the inferior *cul-de-sac*, was a tumor, a little elongated, about the size of a garden pea, and at the summit of which was an ulceration showing ragged and perpendicular edges, and giving out a little pus. This tumor, we said, made substance with the conjunctiva, under which it was imbedded, in the form of a *spindle;* it adhered completely to the mucous surface. It showed exactly the characteristics which a primitive specific ulceration on the preputial mucous tissue would present. The eye was very red, and secreted a little, especially at night (*palpebro-bulbar conjunctivitis*).

A large pre-auricular ganglion, of the size of a full grown hazelnut, which could be felt under the finger, aided in the diagnosis. In the meanwhile, as the patient could not recall any recent *accouchement* with infected women, on whom she had attended, and as she affirmed that she had not submitted to any suspicious embraces, I sent her to M. Ricord, who, after an attentive examination, returned her to me with the following diagnosis: chancre of the conjunctiva, with its symptomatic adenitis. Following the advice of my wise *confrère* and friend, I cauterised the ulceration on the 3d of February with nitrate of silver. On the 4th, ten leeches were applied over the pre-auricular ganglion; on the evening of the same day, a saline purgative was administered. On the 5th the ganglion was less tumefied; the conjunctival tumor had not improved in diminution. I am ignorant how this case terminated, the patient failing to return to the clinic.

These two cases, similar in detail to those with which I commenced to speak of chancre of the eyelids, appear to me sufficient to complete the history of chancre of the conjunctiva.

Syphilides.

I have never had occasion to observe the *pustulous plates* (*plaques musqueuses*), nor, as A. Smée, the coppery eruptions (IV *Annal. d' Ocul.*, vol. xiv., p. 31), on the oculo-pa pebral conjunctiva; but in the generality of cases, I have found on this membrane, tuberculous syphilis. For instance, an example: A man, an old *valet de chambre* of the Duke of Montpensier, came from Spain to Paris to consult me in regard to a grave affection of his eyes. When I saw him for the first time, he was suffering with a double iritis, which became very intense, especially on the left side. The pupil was not slow in closing, and I perceived upon the iris those tumors which I have described under the head of *condylomes*. One of these, larger than the others, situated to the outer side, made a protuberance under the conjunctiva, through the sclerotica. At the same time on all sides of the conjunctiva, I saw raised above the level, small indolent tumors, very hard, oblong, exactly like syphilitic tubercles, which, as those to the side of the ocular apparatus, covered equally the integuments of the body. The skin of the eyelid was pierced through and through. This man, whom I saw with M. le docteur Horteloup, *Médecin de l'Hotel Dieu*, was in such a weak condition, that we deemed it dangerous to resort at the time to a specific treatment, on which we had not indeed decided, except conditionally, the patient asserting in the most energetic manner that he had never had any symptoms of primitive infection. I have learned since that the patient (who quitted us) was treated by Dr. Boinet. At the very beginning he instituted a specific treatment, and performed in the end a complete cure. The left eye, however, remained entirely lost. I have likewise determined for myself the cure, for the patient revisited me many months afterwards. Here the success obtained by antisyphilitic medication was a proof that, notwithstanding denials on the subject, we have had tuberculous syphilides of the conjunctiva.

SUCCESSFUL OVARIOTOMY.

By HAZARD A. POTTER, M.D.,

Geneva, New York.

Jane Kielte, aged 38 years, unmarried, has been suffering with ovarian dropsy for the past two years. The disease having reached that point where an operation becomes the only alternative, I decided to operate, which I did on the 23d ultimo. Chloroform having been administered by Dr. George N. Dox (to whom the patient belonged), an incision was made, about four inches in length, between umbilicus and pubes; slight adhesions were separated with the hand, the fluid evacuated, and the right ovary removed. The tumor and contents weighed eighty-five pounds. The left ovary, being diseased, was also taken away. The pedicle was about five inches in breadth. I divided its peritoneal covering by a slight stroke of the knife, and ligated the pedicle with its main artery, and also one smaller artery, by separate ligatures, between the incised peritoneal edges. The ligatures were removed through the incision.

From experience, I am led to the opinion that when any portion of the peritoneum is ligated, the causes of peritonitis are greatly multiplied, and the chances of recovery correspondingly lessened; the character of that coat is such as to resist the removal of the ligature for a longer time than is usual when arterial or other tissues are ligated.

I divide the peritoneum entirely around the pedicle, ligating separately any smaller arteries that may be cut, tie the main artery between the incised peritoneal edges, and thus exclude the peritoneum from the ligated parts.

The actual cautery, clamp, and other appliances, which have undoubtedly been made effectual in some cases, are scarcely equal to the well-tried ligature, which has so long and so successfully met the demands of surgical science and art. The mortality in ovariotomy arises not so much from the immediate effects of the operation, as from the morbid and debilitated condition of the system when the operation is performed.

Remedial measures are tried until every hope is banished, and when the unfortunate patient dies after ovariotomy, surgery is condemned for its inability to save life which was already a forfeit to disease. By operating as early as possible, we may modify to a great and favorable degree the mortuary statistics of ovariotomy.

It is now eighteen days since the operation, and our patient has made a rapid recovery.

Geneva, N. Y.

TRAUMATIC DESTRUCTION OF THE POSTERIOR PORTION OF URETHRA,

SLOUGHING OF SCROTUM AND RESTORATION OF PARTS.

By GEORGE WILSON, M.D.,

NEW YORK.

The case was one of traumatic destruction of the posterior portion of the urethra of some ten inches in extent, with sloughing of a large portion of the scrotum, so that both testes were freely exposed to view, with restoration of the continuity of the parts. A young man, about twenty years of age, a painter by occupation, was engaged on a warm day in June, in painting the front part of a three-story house. At the time of the accident, he was standing on the window-sill of the second-story painting the outside sash; on raising his hand up to push down the top sash, he lost his balance, turned a somerset as he fell, and landed astride the iron railing in front of the area, which was slightly bent by the weight of his fall. He was conveyed to his house; and on examination, I found a fracture of the pelvis on the right side through the pubic portion—with laceration of the lower portion of the penis involving the spongy, and as I afterwards thought, the bulbous portion of the urethra, with severe contusion of the scrotum and testes, so that through the wound there was a strong seminal odor, which at the same time caused me considerable uneasiness for fear of loss of one or both testes. After bringing about reaction, which was very slow, however, the nervous shock being so great, the first thing he complained of was a feeling of fulness in the region of the bladder, with a desire to urinate, and an inability to do so. After some difficulty, I finally succeeded in introducing the catheter, and drew off a large quantity of blood, which, from the heat of the body and the weather was inclined to coagulate, and which added greatly to the difficulty of getting it to flow through the catheter. I judged from the hæmorrhage, that the bulbous portion of the urethra was involved in the laceration, and that the hæmorrhage came from the artery of the bulb. In the course of a couple of hours I again introduced the catheter, and found that the hæmorrhage still continued, and drew off a considerable quantity more of blood. I then surrounded the scrotum and hypogastric region with pounded ice, and allowed the catheter to remain in the bladder, and in this way I finally succeeded in arresting the hæmorrhage. At the same time I kept giving him stimulants, and in that way managed to keep the life in him, which at times seemed to be fast ebbing away. The next morning, I was suddenly called to see him, as his attendant thought that he was dying, and I do assure you he was very near it. I was by his bedside, and gave him carb. ammonia dissolved in brandy and water until he gradually rallied; he had one more sinking turn, and after that he went along and made very fair progress towards recovery. The contused parts went on sloughing, so that finally the catheter was exposed for some two inches in extent; then followed purulent infiltrations in the scrotum, which were relieved by free incisions; then came sloughing of the scrotum in which both testes were freely exposed, so that as the scrotum lay upon a cushion which supported it you could take them between your fingers. The catheter I kept constantly in the bladder, removing it about once in twenty-four hours, as at the end of this time there was considerable deposit of earthy phosphates upon the end of it, which caused considerable distress to the patient on withdrawing it, and also retarded very much the healing process, owing to the rough accumulation lacerating the parts on its withdrawal, and undoing all that I had done in getting the parts to heal. But by steady perseverance day by day, we gained little by little; the parts began to heal kindly, the deposits on the catheter grew less and less, and still keeping the catheter in the bladder until the parts had all grown over it, and by drawing the scrotum together, we succeeded in getting that to heal also with nothing to open; so that to all appearances he was as good as ever, as far as practical purposes were required. The testes gave me no trouble, and I presume that they were in their normal condition. He got married afterwards, but whether he ever had children or not, I do not know. The fracture of the pelvis I treated with a broad leather belt, which was made to buckle snug around, and which answered all the purpose for which it was required. I attribute the recovery in this case in a great measure to the patient himself. At the time of the accident his system was in a very good condition; he possessed a great deal of nerve, very sanguine and buoyant in his temperament; he had a good deal of what is called *vis vitæ* or tenacity of life. Had he not possessed this physical organization, he would most undoubtedly have sunk; but possessing it, he rallied, clung to life, and recovered.

Original Lectures.

ON NECROSIS AND REPRODUCTION OF BONE.

DELIVERED BY

Prof. JAMES R. WOOD, M.D.,

AT BELLEVUE HOSPITAL, N. Y.

Gentlemen—I propose to say a few words to you this afternoon on the subject of mortification, caries, and reproduction of bone. Ulceration in the soft parts has its analogue in the osseous tissues, and is known by the name of caries. Then again you have the compact, bony tissues dying as well as the softer ones, and this death is called necrosis. They slough as the soft parts slough, and are cast off, thus constituting what we call exfoliation. This state of things, produced in consequence of violence, may be due to constitutional troubles, or mechanical and chemical agents. The bone may be injured, so that that which begets bone (the periosteum) may be directly destroyed by the violence inflicted, or by the inflammation which takes place subsequently; consequently, this injury to the periosteum and the endosteum will cause necrosis on the one hand or caries on the other. If the man is of a strumous or scrofulous diathesis, he may have this peculiar vice engrafted upon the periosteum or endosteum, and he will have what is called the strumous or scrofulous necrosis. A man who has the tertiary form of syphilis, will have a peculiar inflammation of the pericranium, or what is called corona veneris, or inflammation of the periosteum, or any of the other superficial bones; or he may have what is called a node. Then you will see cancer and heterologous deposits in and upon bone, producing necrosis and mortification. In other cases you will find, as in this specimen I show you, the effect of the chemical agent, phosphorus. The fumes of phosphorus killed this jaw, after exciting inflammation in the periosteum.

We commence with the proposition, that no matter whether the periosteum be superficial or central, upon the surface of the bone, or lining the medullary canal, this fibrous membrane is the matrix of bone; and without it you cannot have osseous tissue. You may have the various salts of lime or calcareous deposits

taking place independently; but without the agency of the periosteum no Haversian canals are produced —in a word, true bone is not there. It is the disease of this matrix, this mother of bone, that causes necrosis. If you interfere with, and separate the pericranium and the dura mater, the external fibrous covering of the brain, you cause the death of the bone. Precisely this occurs in Pott's tumor of the scalp. There is more or less contusion at first; then after a few days or weeks there is considerable pain at the point of injury; and by and by the brain is disturbed, and soon after he will have a rigor; and upon examination there is a little puffy tumor of the scalp. What has taken place? The pericranium has been separated from the bone; and you will find that this tumor is always an index to trouble like this. It tells you that the bone has been robbed of its periosteum or pericranium, and that there may be trouble below. The constitutional symptoms also direct you to this. You cut into that tumor, and what do you find? You find bone like ivory in color, presenting none of those little red points which are shown in bone that is covered by this fibrous tissue, or pericranium. You cut through this, and you find that the pericranium has separated from the bone, and that there has been suppuration here, shown by the presence of pus.

If the external periosteum be diseased, contused, or inflamed, you will have what is called peripheral necrosis—necrosis confined to the outer layers of the bone. But if you have the internal covering of the bone, the endosteum, diseased or inflamed, and separated from the bone, you will have internal necrosis, or you may have death of the whole bone. In the first instance you will merely have, what you saw in a case a few days ago, where I chiselled out a portion of the tibia of a man who came here to have his leg amputated because of this disease. I chiseled away the necrosed portion of the bone, and found that it was a case of peripheral necrosis. He had talipes equinus, for which I cut the tendo Achillis; and now the patient is able to put his foot upon the ground; and I find that the periosteum is extending itself, and covering up the opening in the bone, filling up the gutter made by the removal of this necrosed tissue, and he will soon have a very good leg; much better than any artificial limb that could be made.

Let us see what will take place if the bone dies. Suppose, for instance, there is inflammation in the external and internal coverings of the femur, the periosteum and endosteum; the result will be as I show you in this case. I examined this case from time to time—the stump was not closed, as it was at a time when we had a great deal of trouble here because of pyæmia; and I saw this bone cast off because the endosteum and periosteum were separated from it. The patient died; and you see in this specimen how beautifully nature sawed through that bone. The bone separated just as the soft parts separate when dead, the absorbents doing their part here also. Up to the limit of destruction or separation of the periosteum, there is death. Here the line of demarcation is formed, and the periosteum throws out a soft pulpy matter which is deposited between the healthy and unhealthy tissues and the absorbents, and saw through the dead bone and set it free. They did so here, and I removed this piece of necrotic tissue.

It is because of this pathological condition of bone that the great majority of amputations are performed; and until very lately advantage was not taken of the physiological functions of the periosteum, little respect was paid to this insignificant membrane, and reproduction of bone was not sought after.

You will find, if you look through your works on surgery, that statistics will show that the great majority of amputations, except in time of war, have been performed for necrosis of the bone. Surgeons have heretofore cut without regard to the periosteum; they have looked for the dead bone without any respect for that which in the beginning makes the bone, and that which only makes it to the last. You will find in your operations for necrosis, that if the periosteum is not respected, you will increase your original trouble, and may in the end have to resort to amputation.

I used to amputate such limbs, within these walls; and I am sorry to say that I have cut off a great many limbs that I perhaps ought not to have removed. But I did this in accordance with the best knowledge we then possessed, believing in common with others that unless I did so my patients would die; and they would have died, had I done nothing. The periosteum was being destroyed, and this destruction of bone and periosteum was extending to the joints; and when the joints were affected, the constitutional trouble was so great that unless I amputated the limb my patient must succumb. But I am glad to be able to say that it is not a common thing for me to perform an amputation now. Conservatism in surgery is being established, which allows us to cure these cases by a knowledge of the physiological function of that little thin and insignificant membrane which is spread over the bone and lines the medullary canal of the bone. You are to be careful to preserve the periosteum. If you have a patient with deep-seated agonizing pain in the limb, with rigors which do not observe periodicity; though you may not observe periostitis, do not wait for matter to come to the surface; do not wait for this matter to bore through the bone, and then through the periosteum, separating it from the bone, and macerating and digesting it, until there is nothing left of it, as we once did; but cut down upon the bone as you would in syphilitic periostitis, or in the old Corona Veneris. Cut down through the periosteum to the bone, and let the matter escape. Make free that tense membrane which is producing all these constitutional troubles, and if this pain is persistent, it may be necessary to take a small trephine and cut down into the medullary canal. In many cases, before you reach this canal, you will prove the correctness of your diagnosis; you will find that there is a bony abscess there, and periosteal inflammation. In this way you can save a great many limbs; and even after a large portion of the bone is mortified, you will be enabled to save the limb, and to reproduce the parts destroyed.

You see, in specimens, numerous openings leading to the internal portion of the bone. These canals leading from the periphery to the centre of the bone, allow the matter to escape. Nature has done this, and has told you what you ought to do. She does it with the absorbents; you are to do it with the scalpel and trephine.

Take for example a simple whitlow. Some of you, I presume, can hold your crippled fingers up as monuments of bad surgery. Many of you have had periosteal inflammation; matter has formed beneath the periosteum of the last phalanx, if it be in that locality, and has been allowed to remain until the bone has been destroyed. Now, if you had only carefully enucleated the periosteum from the bone, although it were dead it might have been taken out and another one been produced. We do it here in the hospital every day. This fact is important. Supposing a man has whitlow on his index finger, it is important that the last phalanx should be preserved. All of it should be preserved, especially in a mechanic. This is a rule which you should always observe. Every line of the finger on the organ of prehension of the laboring man is of the most vital im-

portance to him, and hence you cannot be too careful to treat them properly.

Let us now consider the reproduction of bone. I have been engaged for the last twenty years in reproducing bones, and with success, as my specimens will show. It was not until I had read Duhamel, that I conceived the idea that this subject would be of so much value and importance in the saving of life and limb. Up to the time of Duhamel I will say nothing with reference to the experiments on the reproduction or growth of bone. He taught that the periosteum produces and reproduces bone; and if you look over the literature of this subject, you will find that he had a very warm contest with Haller and his contemporaries, because he sought to give the importance to the periosteum that he did. Duhamel and Flourens by experiments upon beast and bird, proved beyond a doubt that periosteum was the agent that reproduced bone. He looked at fractures and noticed what occurred after the accident. He saw that there was a thickening of this periosteum; that while in the normal state it was so thin that it was difficult to remove it from the bone, it had now become much thicker, and he became convinced that this was the matrix of the bone. He tried experiments upon rabbits, fracturing their limbs; exsected portions of bone from a number of animals, and united the parts by a reproduction of bone depending upon the periosteum. Sides were taken, and a great deal of controversy was the result of this theory of Duhamel's. In 1847, Flourens, of Paris, published his experiments and their results to the world; having practised all of Duhamel's experiments, and duplicated them, he established beyond a doubt that not only the periosteum reproduces bone, but also the lining of the medullary canal, the endosteum. Before this work appeared I was engaged in study upon this subject, and I examined a great many fractures to ascertain how the callus was formed, and what deposited this callus, and I went so far as to separate all the soft parts except the periosteum from the fractured ends of the bones, and placed the parts in such a position that I could see, from day to day, and from hour to hour almost, the process of reproduction. I performed a number of experiments upon bone; and became satisfied that there was a great deal to be practised that would be conservative in surgery, and that would save life and limb. I therefore commenced the enucleation of bone. I had read all I could find upon the subject, and consulted John Heunter, and many other authors; [and there was but little in our speciality of the profession that he did not investigate intelligently, although but a carpenter by trade.] You will find that at an early period he burned with the actual cautery the foot of an ass, and destroyed the soft parts including the periosteum, leaving the bone dead below, and he saw that the periosteum and adjacent tissues, as he thought, reproduced bone, and thus filled up the chasm which had been made by his actual cautery.

I do not propose to-day to treat this subject *in extenso*, but to illustrate all that I have said, and more too; by the experiments that I have made, I have reproduced nearly all of the bones of the body, and have the proofs before you that what Duhamel and Flourens did upon the brute and the bird, I have done upon the human subject.

The experiments which Duhamel made were with a view of proving that the periosteum was the matrix of the bone, and that it was the only organ that reproduced bone. But Flourens believed that there was a tissue within the bone, a tissue comparable to the periosteum that would also produce bone, and he made his ingenious and beautiful experiments to prove this. He drilled a hole through the bone and introduced into it a silver canula; he then separated the endosteum from its connection with the bone, and left this canula in this position. By-and-by it grew little by little into this canula, and made its appearance at the outer opening. He united this with the periosteum, and he secured a bony connection between the periosteum and the endosteum, growing through this canula. He then promulgated to the world that he could make bone, multiply and duplicate bones at his own pleasure—and he told the truth, for it can be done.

Now I wish to refer to the recent theory, for such it should be called, with reference to the internal periosteum. It has been taught by one or two physiologists that there is no internal periosteum, but that there are what are called bone cells in this medullary tissue, and that when these cells are inflamed bone is deposited, and in this way the internal growth of bone is established.

Fifteen years ago, or a little more, there was a patient in this hospital who had phthisis, and an abscess formed on the side, opened, and led to necrosis of the rib. I carefully took out this piece of necrosed bone from this rib, and in the course of eighteen months this poor woman died. I examined and found that a portion of the rib had been reproduced perfectly, as you see here, by the periosteum which I had left. The continuity was perfectly established, and I was, of course, made glad by my efforts, and encouraged to go on. And I have done so, and established the continuity where it was lost, in many of the bones of the body. Now these facts speak for themselves, and we cannot do away with them. They are truths, and they are now being realized as such by the profession.

Here is a specimen taken from a case in which I removed the greater portion of the clavicle, leaving as much of the periosteum as I could; and you see how bountiful nature has been, or how bountiful this matrix has been. She has given us an exuberant quantity, it is true, and shortened the bone a little; but she has made firm the continuity which she has established. This is really a beautiful effort, and let me assure you that having become engaged in this process of nature you will become so enamored with it that you will hardly be willing to amputate a limb, or to perform a surgical operation where the periosteum is implicated, unless you have previously made an effort to save it.

Here, gentlemen, is a patella which was taken from a child about ten years old. The bone was very much diseased, and I cut down to attempt to free the abscess in which it was swimming, and being digested. I saw that there was inflammation about the joint and synovitis; but the ulceration did not extend into the joint, nor did it extend through the periosteum and the tissues which surround the patella. I enucleated this; and after several months, when it was presented in this theatre, the patella was twice the size of the opposite one, but all the motions of the joint were complete. It is well known that ordinarily when a disease of this kind obtains, amputation is, or has been, almost uniformly the result. But it is now an established point that with care you can make a new patella.

Here is a portion of bone which I removed from an old lady by enucleation; I separated the periosteum from the bone; and although the bone would not sustain itself after I had removed this portion, I succeeded, by splints, in keeping it in position until the periosteum had deposited sufficient osseous tissue to give her a good and substantial arm.

I have here also, portions of the tibia that I have removed; and in all of these cases new bone has been

produced. Here you see nearly the whole of the tibia has been removed. This specimen proves, not only the doctrines of Duhamel, practised by Flourens, but it also proves the experiment that I alluded to as bearing upon the function of the internal fibrous membrane, whether it be periosteum or bone cells. The next is a specimen taken from a man whom I found in this hospital some years ago, who had his leg jammed. He stubbornly refused to have it amputated. I saw him in the hospital, and found upon examination that the periosteum had not been destroyed, although nearly the whole of the shaft of the bone was dead. Little islands of bone were found deposited under the periosteum in that pulp which is secreted and deposited, and which beomes periosteum and bone. You see here that we had an internal growth of bone, and subsequent death, and the internal periosteum contained this sequestrum. Here is nearly the whole of the tibia, which I removed; this beautiful specimen shows the death of the old bone, and the effort which was made by nature before death, to make a bone within the old bone; resulting, as you see, in the formation of a shaft which nearly fills the medullary canal of the tibia in which it was formed. I enucleated the periosteum from this bone, and gave the man as good, and a stronger leg than the one which was not diseased, because where you reproduce such tissue the bone is always larger.

These different bones are reproduced, gentlemen, and the patients leave the hospital perfectly well; and this subject might be continued until I had shown you specimens of all the bones of the body which have been removed in this way and with this result.

In using your instruments for separating the periosteum from the bone, you should take great care, and wait until it has gained some firmness, because of the deposit you are anxious to effect, or you will destroy this new bone. Therefore, you are to treat it very kindly, to enucleate it gradually, and at long intervals, with the instrument best adapted to the case; and as you separate it you discover that it becomes hard, and you completely pass around the bone in this way.

In this case occurring in the thigh, a portion of which I show you, I cut down upon the bone, and found between it and the periosteum, matter. An opening was made, extending from the periphery to the medullary canal, incising the periosteum about four inches; the bone was found dead. I enucleated the periosteum from time to time from this segment of the femur, and found a fistulous opening extending to the medullary canal, and saw the periosteum throwing out crystals of bone, if you will allow the term, until a new femur had formed. At the time of the operation by which I removed this necrotic mass, the new bone was about half an inch thick.

Now, how would you remove that bone? How could I get that bone through without destroying the new bone? This opening was at the lower extremity of the diseased bone. With a small trephine I made an opening through the new bone down to the old one, opposite to the opening which existed, and then, with a chisel and saw, I mortised out a piece of the new bone; and reaching the dead bone, removed the segment of this femur, comprising the whole circumference of the bone, and being about four inches in length. Now, my patient had as good a femur as he ever had; the bone was firm, and he walked without any trouble, and without limping. There are very few thighs saved where this condition of things exists, unless the surgeon has fully considered the physiological function of this maker of bone Now, if I had attempted to remove this dead bone, which I hold in my hand, before the new one was sufficiently deposited, I should have destroyed all chances of saving that man's limb; but by careful enucleation practised for some two months, the result desired was obtained.

I have here all of the superior maxillary bone of the right side except the orbital process, and a portion of the superior maxillary bone of the left side. The patient from whom this specimen was taken was a lady who had inflammation of the periosteum and loss of her teeth, and came to me with disease of the superior maxillary bone. I made an incision along on the side of the gum cutting down to the periosteum on the inside and outside, and by enucleation separated this bone, and as I gradually separated the periosteum from the bone, the bone became hard and dense, and she had a new jaw without any deformity. She wears artificial teeth, and you would not dream that she had lost her jaw.

Here is a specimen taken from a patient from whom I removed the whole of the lower jaw. I wish you to remember the importance of making your incision in this operation, beneath and behind the jaw as much as possible, in order that the cicatrix, when it forms, shall not disfigure the patient.

I have here two jaws which were recovered from the effects of vapor of phosphorus. In this case, which was of a young lady, the periosteum was enucleated and the reproduction of a new jaw was the result, with very slight, if any deformity. This girl, when she got well of this operation, left the hospital with a new jaw, returned to her old friend and employer, and again engaged in the manufacture of lucifer matches. She had a decayed tooth in her upper jaw, which was removed, and the vapor then attacked the periosteum of the left upper jaw, and I removed the most of this, and reproduced the jaw. So I not only reproduced this portion of the upper jaw, but the whole of the lower jaw complete, and I believe this is a unique specimen.

In this other specimen which I show you of the reproduction of the lower jaw, all its motions, functions, and processes are complete. You see the processes to which the muscles passing between the hyoid bone, the tongue and jaw, are attached, and you observe that the coronoid processes are perfect, reaching up under the zygoma; and more than this, you perceive, what is denied by many, that the surgeon can reproduce a joint. Many operators will tell you that you cannot reproduce a joint where you have removed the bones forming it. But you see here the condyloid process shining beneath the synovial membrane, with the cartilage of incrustation and the ligaments attached to it, performing all their functions. The synovial membrane, the cartilage of incrustation, and the ligaments, are intact, and all the functions of the jaw are perfect. This poor girl died subsequently of abscess of the brain.

You can even do more than this sometimes. I was asked by a gentleman, who had heard me describe this operation and its results some time after that reproduction of the lower jaw, "if the teeth were through yet in the new jaw?" I told him they were not. But, gentlemen, I have left the old teeth in the new jaw; and this specimen was taken from a patient that I operated upon in this hospital with this result. I enucleated the bone, and found that the four incisor teeth were becoming firmly attached to something. I separated carefully the bone beneath the periosteum which was becoming solidified, and I discovered that the teeth were being embraced by the new bone, that it was forming a cast round about the teeth, and at the time of the operation, after I had enucleated and made solid the periosteum, I lifted the old bone out, and left the patient's teeth in the new jaw! Eighteen months after this operation my house surgeon, Dr. Phelps, and myself saw

her, and the teeth were very firm, and as useful as they were in their old place.

There is a point to which I wish to call your attention, viz., with reference to the notions of those who did not believe that the periosteum and endosteum produced bone. They contended that the periosteum and the tissues in the neighborhood of the bone reproduced it; and before, at the time the chemist discovered that there were such deposits as calcareous deposits, this was brought up as proof that the tissues in the neighborhood of the bone reproduced bone, as well as the periosteum. This specimen is simple and to the point. Here was an extensive abscess forming in the bone, and going through, making an opening at or near the lower end, like a tent, separating it, as you see, some inches from the bone. I found new bone was forming in this extended periosteum so remote from the bone, layer after layer; and in this way was produced this bone which I show you. This to a great extent explains away and disproves the theory that other tissues than the periosteum reproduce bone.

We have also seen that the periosteum will not only reproduce bone, but will extend itself, covering the bone, and extending itself over the ends as well as the lateral portions of the bony tissue.

Now I maintain, that when the periosteum is inflamed or lacerated it will grow into other tissues, if allowed to do so. Here is a case of luxation at the hip, occurring during morbus coxarius. You see the upper border of the old acetabulum destroyed, and you see here a partial dislocation upwards of the head of the femur; and the ligaments, because of the periosteum that has been extended to them, have ossified; and in this hard and ossified material you may discern the impression of the fibres of the capsular ligament, and the cervical ligaments.

I have two more specimens that I wish to show you before closing these remarks. This leg was taken from a boy who had a strumous cachexia, who had periostitis and ostitis. I made an incision the whole length of the tibia, and through the periosteum down to the bone, which was dead, and a portion of the periosteum on the anterior surface of the tibia was also destroyed. Nearly the whole of the tibia died. The boy was weak and feeble, and I gave him nourishing diet—iron, phosphates of lime, and everything that could nourish him, and make his blood plastic, and calculated to administer to the wants of the periosteum; and then I commenced enucleating the periosteum from the bone—and you see how far I had advanced. I had enucleated the periosteum from time to time on this dead bone—and you see the new bone is deposited in it—all along the side of the tibia, and in a little while I should have had that dead bone out, and a new tibia formed there in its place. But one day I was called to see him as he had had a rigor and terrible pain at the upper and lower end of the tibia; and his ankle-joint was terribly swollen. I found there was synovitis about the ankle, and that his constitution was terribly shocked by what was going on. There was matter in the joint, and to save his life I amputated the thigh. On making section of the bone I found tuberculous deposit at the lower end of the bone communicating with the ankle-joint—and also a tubercle deposited at the lower end of the tibia.

I have a great many other beautiful specimens by which I can illustrate this important subject; but I only propose to-day, to give you an idea of what can be done in the way of conservative surgery, by the reproduction of bone. I can exhibit to you but one more specimen, and give you the history of the case. This portion of the thigh bone, about six inches in length, I enucleated in a man upon whom I finally performed amputation. The bone died, the stump was not closed, and I had an opportunity of watching the growth of new bone from the time the old bone became necrotic, until I removed it by enucleation. In this case at the time of enucleation there were three firm, well formed bony cylinders; the first and peripheral, formed by the external periosteum; the second, the sequestrum of the old dead femur; and the third, formed by the internal periosteum and bone-cells. From between the first and second I removed this, the old femur, the specimen I now present to you. The thigh bones, for we must use the plural here, are at least four times larger than the original femurs. This is one of my most valuable specimens, as showing the reproduction of bone, and deposit of tuberculous matter in bone.

JEFFERSON MEDICAL COLLEGE

OF PHILADELPHIA.

Surgical Clinics of Prof. Gross.

ENLARGED SPLEENS—DIFFERENTIAL DIAGNOSIS FROM OVARIAN AND OMENTAL TUMORS.

Case I.—*Enlarged Spleen.*—August T——r, æt. 25, employed in a manufactory of gas fixtures, has been in the U. S. service four and a half years—temperate in his habits. He was sick seven or eight years ago, and says he took a great deal of quinine, his account of his case pointing to a probable attack of intermittent fever. There is great enlargement of the abdomen, with an appearance very much that of ascites; and on examination, though there may be water present in the abdomen, this is by no means the sole cause of the swelling. There is a tumor occupying a large portion of the umbilical and left hypochondriac regions, and a portion of the iliac region. The tumor projects towards the right side of the umbilicus, and its outlines can be distinctly defined when the limbs of the patient are flexed so as to relax the abdominal muscles. It is a sharply defined tumor, projecting back into the ileo-lumbar region a considerable distance, under the ribs of the left side as high as the ensiform cartilage. Its surface appears to be uniform, there is no nodosity, no lobulation of the surface, it is perfectly smooth, and its edges sharp. It is more distinct on the outside of the tumor and below, not so much so above. The patient is feeble and emaciated, and has lost a good deal of flesh. He complains of having terrible pains last week, which he describes as "frightful, so that he could not rouse himself on account of them." When the weather changes, his pain increases. Appetite tolerable, tongue somewhat reddened, moist, and expanded; bowels regular; sleep poor; urine brownish-yellow, about a quart being voided every night; no cough, no palpitation of the heart; no fever at night, but a good deal of perspiration. The probability is, however, that there may be a slight febrile condition at night without the patient recognising it.

The history of the case points to the nature of the enlargement. We have reason to believe that the patient suffered seven or eight years ago from intermittent fever; which, when long continued, is likely to give rise to enlargement of the spleen, which is a fact very well known; and this enlargement frequently continues to an enormous extent, so that it may acquire a weight of five, eight, ten, or even fifteen pounds. This tumor will be hard, firm, and resisting, and will extend by and

by in every direction, so as to encroach on the diaphragm and everywhere on the walls of the abdomen, descending even into the pelvis.

This appears to be the nature of the present case, a chronic enlargement of the spleen originating in a miasmatic fever, and slowly and surely enlarging and undermining the health. In some cases of this kind the inflammation which always accompanies enlargement terminates in ulceration. This is a rare event. Dr. Gross has seen one such case, and but one in his entire experience. There is another circumstance in reference to the diagnosis of this tumor, and that is its outline and its situation. It lies on the left side where the spleen is situated, and the tumor has a sharp outline, and a well-defined margin, much more so than an enlarged liver would have. In the female such a case might be mistaken for an enlargement of the ovary. It might be mistaken for an enlargement of the omentum, which is liable to canceroma and hypertrophy, sometimes forming an enormous tumor; but then this lies in front of the bowels nearly equally on both sides. It is liable to irritate the peritoneum and produce ascites, as will all tumors of the abdomen or pelvis. Another effect is pressure on the diaphragm, producing difficulty of respiration. There is also some pain from pressure on the surrounding parts. The patient lies on the right side.

Treatment.—The patient will be given four times a day 15 grains of the hydrochlorate of ammonia in solution. If there is pain at night, an anodyne should be administered. He should take a concentrated nourishing diet, with milk punch; and locally employ one part of biniodide of mercury to eight parts of simple cerate. This is a most powerful stimulant to the absorbent vessels.

Extirpation of the spleen has been occasionally resorted to from the sixteenth century even to the present time; but the operation has usually proved fatal. Portions of the organ extruding from wounds of the parietes have been occasionally excised; and as in the case of Powell of Covington, Ky., the patient has recovered, showing a tolerance of interference by this organ. The removal of the spleen in some of the lower animals is known to have rendered them fat and indolent.

Case II.—*Nov.* 21, 1866.—*Enlarged Spleen.*—Elijah A——r, æt. 34, a laboring man, accustomed to heavy lifting. Has had an enlarged abdomen for two years. On two occasions he has been tapped, but at neither time was there any escape of fluid to any considerable extent, about two ounces escaping at the moment of puncture, followed by gradual drainage to the amount of three gallons. There is a good deal of tumefaction of the abdomen, but not to as great an extent as before the last tapping. The increase in circumference during the past six months has not exceeded four inches. On the left side of the tumor, at the bottom, there is some pain, but no pain in the tumor itself; no pain on taking a long inspiration; in walking, pain is produced by the jarring of the mass; the facility of breathing is much embarrassed; at present the patient can lie down pretty low, but a year ago he had to be kept propped in the semi-erect position; the bowels are costive at present, but sometimes they are regular; appetite is strong; sleep is not good, though there is no pain at night, except that complained of on the left side; patient lies equally well on the back or on either side; passes about three pints of urine in the twenty-four hours, and this urine deposits a brick-colored sediment; and once or twice since being tapped he has passed over a gallon of urine; emaciation has been increasing progressively. There is no discoloration of the skin over the tumor, no enlargement of the subcutaneous veins.

The tumor is hard, extending from the ribs down as far as the pubic bone; it reaches far back into the left iliac region; there is a distinct line of demarcation on the right of the umbilicus, with a rather sharp margin well defined. There is resonance on percussion, showing that the intestine is there distended with air; higher up percussion is dull, on the left side it is flat; the resonance forms a line across of about four and a half inches.

This patient states that he has never had intermittent fever; and that the disease came on without any assignable cause.

It is a case of enlarged spleen. The tumor occupies the situation in which the enlarged spleen is usually found, the left side; the surface is smooth and perfectly uniform, there is nothing nodulated about it; it has a peculiar sharpness of border, and its edge is felt nearly at the middle line. It is probably firmly adherent to the parietal portion of the peritoneum. It is not likely that it is an affection of the omentum, which occasionally becomes the seat of disease, morbid formations being liable to form in it, especially colloid, a form of malignant disease of which Prof. Gross has seen but two examples in this particular situation; one occurring, during his residence in Cincinnati, in a man who, four years before, had had a severe attack of cholera, and the other in a wholesale druggist, of Louisville, Ky., both of which were fatal, and the tumors were found to be enormous, extending from the pelvic region as high as the diaphragm, involving the bowels and portions of the liver. The omentum is also liable to take on hypertrophy, a sort of sarcomatous, fleshy, or fibroid enlargement of its substance, in consequence of which it would form a tumor of considerable bulk, but hardly as large as that attained in the tumor under consideration.

With regard to the tumor on the right side, a portion of it is soft and is ascitic, depending upon an accumulation of serum in the peritoneal sac. The patient's medical attendant informs us that he tapped the man, and three gallons of fluid escaped eight days after the operation. Any tumor of this kind fretting the peritoneal surface, will provoke a secretion and produce ascites. There is another portion of the swelling which is solid, where there is no gas, no resonance, no distinct fluctuation. This is possibly an enlargement of the liver, but it may be something else; it is not quite as solid as an enlarged or hypertrophied liver should be. There may be a cyst in the liver, or a cyst over the liver.

This patient has been treated with preparations of iodine. If the diagnosis is correct, the ointment of the biniodide of mercury — one part to eight or ten of simple cerate—by inunction might do some good. The ointment of the shops is too severe for this purpose, it acts as a powerful irritant. During the progress of treatment it is probable that the ointment may be increased in strength, but it is best to begin with it as weak as possible, so as not to excite too much irritation of the skin. It should be rubbed on effectually, once in the twenty-four hours, keeping the surface covered in the mean time with flannel and oiled silk over it, so as to protect the clothing.

Internally we will use the hydrochlorate of ammonia in doses of 10 grains at first, gradually increased to 12, 15, or 20 grs., three times daily, in solution; combining with each dose one-twelfth gr. of the bichloride of mercury. The treatment is sorbefacient, to try and reduce the size of the spleen.

The diet is to be simple, nutritious, and generous.

Absorption of Gases.—Charcoal from the shell of the cocoanut is said to possess extraordinary power of absorbing gases.

Progress of Medical Science.

THE ORIGIN OF PROGRESSIVE MUSCULAR ATROPHY.—Dr. L. Duménil, Surgeon-in-Chief of the Hotel Dieu, at Rouen, reports two cases, the subject of the most careful clinical observation, cadaveric and microscopic examinations. He shows this disease to be due not to atrophy primitively occurring in the muscular fibres, but on the contrary originating in atrophy of the nerve tubes of the trunks and branches supplying the muscles with nerve stimulus. It seems that Schneewogt was the first to signalize this pathological condition of the nerve tubes in progressive muscular atrophy, and that afterwards M. Jaccoud, in 1864, reported two cases.—*Gazette Hebdomadaire.*

HUGE RENAL CYST MISTAKEN FOR CYST OF THE OVARY.—M. Béhier recently presented to the Paris Academy of Medicine an interesting post-mortem specimen of a huge renal cyst, which during life was thought to be an ovarian cyst. The tumor had been tapped twice, and had furnished each time a chocolate-colored liquid, which never presented any of the characteristics of urine. The obstruction of the orifice of the ureter by two large calculi, appeared to be the cause of this cystic tumor. M Béhier called attention to the importance of the diagnosis in this case, and remarked that the possibility of such a mistake should not be forgotten in the operation for ovariotomy.—*Gazette Hebdomadaire.*

RHEUMATISM AND HEART AFFECTIONS.—M. Vernay, in a communication recently addressed to the Academy of Medicine of Lyons, establishes fully by observation, based upon several hundred cases of acute articular rheumatism, the coincidence first pointed out by Bouillaud, of this disease with endocarditis and endopericarditis. He found the coincidence of endocarditis to be the rule, and non-coincidence the exception. He expresses an opinion, however, differing slightly from that of Bouillaud; and which is, that not only the intensity of the rheumatic affection constitutes the danger of endocardiac complication, but that it is also especially indicated by the shifting character of the articular pains.—*Union Médicale de la Gironde.*

ENDOCARDIAL ULCERATION OF SUPPOSED SYPHILITIC ORIGIN.—M. Villard presented to the Academy of Medicine of Marseilles a heart in which one of the aortic valves offered a peculiar ulceration; there were also some small fungous growths on this valve: the two others were by ulcerations, the borders of which were covered with perforated fibrinous excrescences, and the centre of the ulcerations was of a grayish color. Their peculiar color, and the co-existence of eruptions of secondary syphilis on the skin, induced the opinion that this endocardial lesion was of a syphilitic nature.—*Bulletin de la Société de Med., Marseilles, Jan.* 1867, *and extracted from the Union Med. de la Gironde.*

FATTY "EMBOULIE."—It seems that the first cases of papillary distension by liquid fat, and which were especially observed in the lungs, were noticed about four years ago by Zenker and Wagner, and they both attributed this capillary obstruction to an "emboulie" of fat globules. This condition was supposed and asserted by Grohe to be only an agglomeration of fat and blood corpuscles, due to the diminished rapidity of the circulating current immediately preceding death.

Busch, of Königsberg, Prussia, desirous to throw light upon this subject, carefully studied the conditions which favor the phenomenon of fatty "emboulie," in order to determine if this was caused by the crushing of bone containing considerable marrow, as a few cases already observed seemed to show. By experiments on rabbits, in which he crushed the bones of their hind legs, he incontestably proved this fatty embolia to be due to the disorganization of the marrow, and the absorption of its fat globules by the circulatory system. This peculiar accumulation of fat globules has in certain rare cases been observed consecutively in diseases not connected with the bones, as in endometritis and metrophlebitis; but especially in suppuration of tissues containing much fat. Fatty embolia generally does not sensibly affect the health, and appears to be of more interest physiologically than pathologically. The cases in which it appears to have been the only cause of death, and sometimes of sudden death, are exceedingly rare.

DEATH FROM THE ENTRANCE OF AIR INTO THE VEINS OF THE UTERUS.—Professor Olshausen relates a case in which, during parturition, the cervix not dilating rapidly enough, the uterine douche was applied. It was used three times, and about eight minutes after the last application, the patient complained of difficulty of breathing, suddenly rose straight up in bed, and then fell, and after a few convulsive efforts died. Emphysematous crepitation could be produced by pressure on the abdomen. At the post-mortem examination a considerable quantity of air bubbles was found in the coronary veins of the heart. The small quantity of blood contained in the right heart was very frothy. The womb crepitated on pressure; the surrounding vessels were filled with air bubbles, as also the ascending vena cava. The two placentas (it was a case of twins) were detached, and one of them formed with the interior wall of the uterus an inflated pouch.

REMARKABLE CASE OF DEPOSIT IN THE LUNG.—Zenker reports that a woman, whose occupation in a factory exposed her to the inhalation of minute particles of oxide of iron, died a few weeks after exhibiting some of the general symptoms of pulmonary consumption, but with negative results on auscultation and percussion. At the sectio cadaveris the lungs were observed to be infiltrated with the red oxide of iron, which was found to be about two-thirds of an ounce, and of the same nature as that daily used by her in her work, and which was deposited in the tissue of the lungs in the same manner that charcoal dust is seen after death in the lungs of miners and others, who constantly live in an atmosphere of coal-dust. Possibly the Pittsburg doctors have ampler facilities for the study of coal dust and other deposits in the lungs than Zenker, and might elucidate this murky subject.

EXPERIMENTS WITH BROMIDE OF POTASSIUM.—Messrs. Eulenburg and Gutmann have stated, before the Academy of Medicine of Paris, that doses of from thirty to sixty grains, either by the stomach or injected under the skin, kill a rabbit in from ten to forty minutes. Smaller doses momentarily disturb the action of the heart and paralyse the power of moving and feeling, causing a few antecedent shivers. On a post-mortem examination of the animals, no change but some congestion of internal organs is found. With frogs, a subcutaneous injection of one grain to two causes, after ten or fifteen minutes, loss of movement, reflex action, and feeling, with arrest of respiration, weakening and infrequency of cardiac ventricular action, retardation of peripheral circulation, and lastly, complete diastolic arrest of the heart's action. These effects are attributed by Messrs. Eulenburg and Gutmann not to the bromine, but to the potassium.—*Lancet.*

A NEW KIND OF ACARUS.—M. Indée has noticed among the Kabyles of Northern Africa a pruriginous

complaint somewhat like itch; where, however, the acarus, forming a black spot on the skin, moving about with energy, is different from the well-known acarus scabiei. The sulphuro-alkaline ointment destroyed the animalcule. In France, M. Rouyer has noticed in the department of Indre, a papular pruriginous eruption, affecting the country people who had handled the wheat somewhat spoiled by the frequent rains of last summer. The same parasites were here observed.—*Lancet.*

Decapitation.—As is usually the case after every execution in Paris, the decapitation of the brutal murderer, Lemaire, has been followed by statements in the newspapers as to the persistence of sensibility for some time in the head after decollation. M. Bonnafont has, therefore, thought it worth while to give an account, in a recent number of the *Union Medicale*, of some experiments he made many years ago in Algeria in order to dissipate the belief then so generally held in that colony. On the occasion of the decapitation of two Arabs, he had ready a vessel nearly filled with pulverized plaster, and placed on a low table, and a friend and himself were provided with a small speaking-trumpet and a very sharp-pointed probe. Immediately the first head was cut off it was placed in the vessel containing the plaster, in order to arrest as far as possible the hæmorrhage. The speaking-trumpet was applied to the ear of the defunct, and his name well shouted through it, but no movement of the eyes or of any part of the face manifested the slightest perception. The eyes remained dull and motionless, and the face colorless, and scarcely any contraction of the muscles was induced by provoking them with the pointed probe. The second head manifested in like manner signs of instant death; as, indeed, how could it be otherwise than that this must at once ensue upon the syncope induced by the section of the large arteries? The numerous relations to the contrary, as well as the blush on Charlotte Corday's cheek, M. Bonnafont regards as fabulous, and he points out that there is no analogy between this reputed retention of sensibility by the decapitated head, and the fact of ducks and turkeys being able to walk about for some time after decapitation, as shown in the experiments of Aldini and Eugene Sue.—*Quar. Jour. of Psychological Med.*

Effects of Medicines Introduced into the Urethra.—Professor J. L. Crawcour, of New Orleans, has communicated to the *Southern Journal of Medical Sciences* some exceedingly interesting, and it may prove equally important experiments with regard to the constitutional effects of substances introduced into the urethra. He concludes that the portion of this canal bounded by the prostate and neck of the bladder has a remarkable power of absorption, which is not possessed by the walls of the bladder within, nor by the membranous or spongy portions without, this being due to the rich nervous and vascular supply of the part in question. The communication is based upon observation of nearly sixty cases, in all of which a cerate of morphia or atropia was smeared in very small quantity upon the extremity of a silver sound, and allowed to remain in contact with the parts from one to five minutes.

In one case less than half a grain of atropine cerate, ten grains to the drachm, produced complete dilatation of the pupil in three minutes, and active delirium in five minutes. The subject was a hospital patient not suffering from urethral disease. In another case, a portion no larger than a pin-head produced dilatation of the pupil and huskiness of voice in five minutes, and a staggering gait in ten minutes. The effect of small amounts of morphine ointment, one scruple to the drachm, was no less marked.

In one case drowsiness was produced in five minutes, and eighteen hours afterwards the patient returned to be catheterized, paralysis of the bladder having occurred.

The professor does not hazard a theory, the effects obtained appearing entirely out of proportion to the amount of medicine used. He therefore merely submits the facts to the medical public, hoping that in cases of mania and delirium tremens they may be of service, and looking to the future for an explanation.

Aneurism in the Horse.—M. Raymond has published two cases which refer to old horses. The mesenteric trunk was in both instances the seat of the aneurism; and the author observes that very few old horses are dissected which do not present dilatations of the trunk just named. The clot often contains hard substances and parasites.—*Lancet.*

Case of Post-Partum Hæmorrhage, in which the Ether-Spray was Successfully Used.—John Broadbent, M.R.C.S., etc., Manchester, reports (*British Med. Jour.*) a case of post-partum hæmorrhage successfully treated by ether-spray. At 10½ P.M., on April 3d, 1867, he was called to see Mrs. T., in labor of her twelfth child. He found the os uteri only slightly dilated, and the pains weak. The breech presented, and the child was born the following morning, without anything unusual occurring. The placenta was adherent, and required the introduction of the hand for its removal. Profuse hæmorrhage followed; and, though the usual remedies, including ergot, cold napkins to the vulva, etc., and introduction of the hands into the uterus, were employed, the bleeding continued, and the woman became almost pulseless, and was evidently sinking fast. The hands in the uterus moved about as if in a wet bladder, little or no contraction being excited by it. His friend Mr. Harrison saw the case with him, and he proposed to him to apply the ether-spray to the hypogastric region. This he did, using the double jet; and very soon the uterus began to contract and the hæmorrhage ceased. There was no relaxation of the uterus after; and the woman ultimately made a good recovery, though very anæmic for some time after. The hæmorrhage was evidently due to uterine inertia; and the effect of the ether-spray in producing contraction of the organ was very marked after the failure of the remedies used before it.

Nodulated Arteritis.—MM. Kussmaul and Maïer describe a new variety of arterial disease, characterized by circumscribed thickenings of the walls of vessels, commencing with an abundant proliferation of the cells of the middle coat. This *nodulated arteritis* and the muscular paralysis which accompanies it are altogether incurable. Its phenomena are the following:—1. A general paralysis occurs without known cause, and is developed rapidly, with fever, nephritis, and violent muscular pains. 2. This is accompanied by a nodulated peri-arteritis, which, by interrupting the circulation, causes alternate contractions and dilatations of the vessels. 3. The principal diagnostic signs are the rapid development of muscular palsy with loss of contractility and intense pain, the nephritis, the arteritis, and the presence of small arterial nodosities under the skin. 4. When the disease affects the intestinal arteries extensively, it may cause the same changes in the mucous membrane as are produced by embolism. 5. The muscles undergo fatty degeneration, but as long as they have only partly lost contractility they may recover. 6. In order to restore contractility the application of induced, and still better, of constant, currents is desirable.—*Lancet.*

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

THE SCARCITY OF WORKING MEDICAL MEN IN AMERICA.

IT is a deplorable fact, that we have very few actual working men in our country. The desire for large practice has taken such a possession of us that we have lost sight of everything else, and like a dangerously fascinating whirlpool it has swallowed up in comparative oblivion some of the best minds in the profession. A distinguished medical writer has truthfully said, that a large metropolitan practice is the bane of professional progress. To a certain extent, the allurements held out by a large business are such as none can altogether withstand; the possession of a handsome brown stone front, a splendid driving establishment, and a richly furnished office, with the attendant luxuries that associate themselves with a handsome living, are temptations which Americans especially cannot be proof against, and we are fast beginning to think that such is after all the main object to be attained. It is true we occasionally deplore the existence of so few scientific observers in our midst, but our consciences very rarely do more than temporarily upbraid us for our lack of enthusiasm in the prosecution of our studies, and we soon settle down into an apathy which is both enervating and dangerous.

In other countries this is not so. There are greater numbers to be found in Europe, especially, who are constantly laboring in the cause of science, patient observers, careful thinkers, and sound students, who are only content when they are enabled to add some new fact, or make some new discovery, which may not only benefit their race, but their profession. We are often led to envy such, but we very seldom go further.

As an evidence of the want of interest in scientific pursuits, we have but to refer to the paucity of communications of those of our representative men to the columns of the medical journals, and the small number of works that are issued by the American press. There is some good reason for this in a want of something to say, and in an absence of an originality of thought and observation which is always associated with a lack of study and reflection; but even those who are the exceptions to the rule, who really labor for the advancement of their calling, stop just short of doing the most good by the publication of their views to their brethren. With a few notable exceptions, no standard works have been issued within the past few years, comparable with the amount of talent which might be developed by patient industry on the part of its possessors. The standard medical literature of our country is so deplorably deficient that we are still hanging to the skirts of transatlantic authors, and refusing to help ourselves with the abundance from our own storehouses, and develop a home literature that would be a credit to the profession of the Western Hemisphere. Our book authorities can be numbered by a dozen or two, and this in a country peculiarly blessed with the means of most extended observation.

When a fresh graduate first embarks in business he seems fully imbued with the idea that a life of study and hard work is before him, and with the best of intentions resolutely sets himself at it. But how soon does he forget his duty! His microscope is liable to become dirty and neglected, his books quietly rest upon his shelves, and every other interest is lost, save that which centres itself upon a large and lucrative practice. If half the work were devoted to study which is now bestowed upon the hatching of a good bank account, how much better off would be our profession, and of how much more service we might be to humanity! The main trouble is, that we are not content with a livelihood, but must aim for fortunes, and really degrade our profession to the merest trade. A physician's actual worth is not now measured so much by his skill as the extent of his business, and bewildered with the hope for a like success, too many are greedily following in his footsteps.

We contend that no amount of business should deter any medical man from continuing his studies, and with the really industrious man it does not. We know of a few, who, although in extensive business, can always find time and opportunity to unravel the mysteries connected with a post-mortem examination, and even search up the literature of any particular subject connected with a case under investigation; and of others, unluckily greatly in the minority, who devote the early morning hours to reading and research, who never neglect to record their cases as they occur, and who take every pains to inform themselves of what is going on around them, and who are in reality the thinking, progressive, and original men in our ranks. It is not expected that every one will be an originator; but if he cannot lend a helping hand himself in developing the resources of our art, it is his bounden duty to keep himself at least informed of the doings of others, and take every advantage which experience and observation can give. But so seldom is this done that the performance of such a duty is an exception to the rule. We have known physicians who have allowed books upon subjects which should materially inter-

est them, to remain for months upon their tables without the leaves being cut, and journals to lie piled in the corners of their rooms not even divested of their wrappers. This, we will admit, is an extreme case, but a great majority of our practising physicians do not do much more.

In times gone by the actual making of money was considered as secondary to the study of disease and its phenomena; there was that ardent desire for advancement and discovery, which centred itself in the renowned John Hunter, who, when disturbed in the midst of his experiments by a patient, only reluctantly left his subject, because he thought his family might have a use for the guinea on the morrow. There are too few who practise on such a principle, too few who would develop such a relish for improvement as would enable them thus profitably to fill in their spare hours.

It is shameful, too, to notice what a small amount of work is done in our large societies. We might instance that of the American Medical Association as a striking example. Year after year committees specially appointed to report on different subjects fail to make any reply; and the majority of their members, although appointed with reference to their qualifications for the task, do not care even to offer a reasonable excuse for the non-performance of a duty. Then again the comparatively small number of competitors for the prizes is another indication of the growing indisposition to do anything more than the mere attendance upon their patients involves.

We are not led to make these remarks in the hope that we can offer any particular remedy for the evil, but merely to allude to its existence as an explanation for the paucity of standard works among us, the small number of illustrious names, the almost total absence of original observations compared with what has been done, and is being done elsewhere.

The recent discussion concerning the status of female physicians which took place before a meeting of the Philadelphia County Medical Society, and was published in our columns, has given our readers an idea of the estimation in which these doctresses are held by our neighbors. Shortly after the report of the same meeting appeared in the *Philadelphia Reporter*, that journal was favored with a communication from a correspondent signing herself Ann Preston, M.D., in which she took occasion to defend the position of female doctors in a manner more vehement than logical. In the same journal appears an answer to the aforesaid letter, in the shape of a communication from J. W. Sherry, of Brooklyn, N. Y., which is so much to the point that we cannot forbear placing the bulk of it before our readers. The principal part of the letter is made up of a series of questions propounded to the fair defender of women's rights in medicine. Here are some of them:

When *consultation* is granted, are women to be admitted to all professional meetings: such as medical societies, medical conventions, medical quizzes, etc., etc., just as far as their "mental cravings" may prompt them to ask?

Does the authoress approve of *women* and *men* studying anatomy over the same dead subject—dissecting in *company* the male or female cadaver?

Does this lady approve of young women walking the hospitals with young men, the medical, and more especially the *surgical* wards?

Does she declare that it is proper and becoming for young women to witness any or all operations in the amphitheatres of hospitals, crowded with men "from pit to dome?"

Does she claim that *surgery* is a legitimate field of study for women?

If so, would she perform an operation for phymosis, fistula in ano, or calculus; or use the catheter on the male patient? Should *any* woman do these? Women *can* be found who can perform such operations. Should they? "To this complexion must we come at last?"

Some twenty ladies presented themselves at a surgical clinic and lecture in one of the New York Hospitals. The surgeon announced that the subject would be *hernia;* and, not wishing to shock the delicacy of the fair auditors, he suggested the propriety of their withdrawal. Several hundred young men were present, and he thought it unfitting that the young ladies should remain. *They did not retire*, but occupied the *nearest seat*, while eighteen *male* patients were exhibited, necessarily *in a state of* NUDITY.

Does ANN PRESTON, M.D., endorse the course of the young *ladies?*

At another hospital, lithotomy was to be performed on a man. Eight members of "the little band of true-hearted women, just entering the medical profession," appeared to witness it. The surgeon, from motives of delicacy, asked them to retire, and he sat down to await the result. But they moved not. He thereupon announced that if they did not withdraw, the operation would be postponed, or done privately. *Then*, they left. Does ANN PRESTON, M.D., insist they should have remained, and that the surgeon should have surmounted his modesty, and have proceeded with the *exhibition* without a protest?

When women have fully attained their so-called "*right*" to practise medicine on an equal footing with men, does ANN PRESTON, M.D., assume that they shall treat any and all diseases that "our flesh is heir to?" Shall they, in the male, treat gonorrhœa, syphilis, stricture, enlarged prostate, and spermatorrhœa?

Shall women handle the genitals of men, apply escharotics to chancres, introduce the urethroscope, examine with digit *in ano* the prostate to find out its condition, etc., etc., *ad infinitum*, *disgustam*, *nauseam?* Is it to such a field that lady practitioners claim a right? And if so, *is* it strange that the medical profession so generally oppose this "great movement," this "evidence of the advancing civilization of the day," this "revolution that is never to go backwards?"

Though the writer may feel that she and her "little band of true-hearted women" are called to do this work, though she may "appeal to heaven to witness the justice of her cause," though she may say that she "will settle the question with her God;" yet there are men and women, the best and purest, the most thoughtful and liberal, who cannot agree with her. Great names and good ones may lend their influence to this "movement," and it may be claimed that the moral sense of the community sustains it, "but there are those who fail to recognise the appropriateness of

women entering an arena containing so many repulsive features, "so many forbidding conditions."

Reviews.

I. CHOLERA, as it appeared in Nashville (Tenn.), in 1849, 1850, 1854, and 1866. By WM. K. BOWLING, M.D., 1866. 8vo., pp. 27.

II. REPORT TO THE INTERNATIONAL SANITARY CONFERENCE of a Commission from that Body, on the Origin, Endemicity, Transmissibility, and Propagation of Asiatic Cholera. Translated by SAMUEL L. ABBOT, M.D. 8vo., pp. 104. Boston, 1867.

III. CIRCULAR, No. V., WAR DEPARTMENT, SURGEON-GENERAL'S OFFICE, MAY 4TH, 1867. REPORT ON EPIDEMIC CHOLERA. 4to., pp. 65.

IV. REPORT OF CITY PHYSICIAN FOR THE YEAR ENDING APRIL 1, 1867. Boston, 1867. 8vo., pp. 152.

I. WORKS on cholera still continue to make their appearance. There is little doubt that the disease will reappear the present summer in many of its old haunts; and indeed, while we write, we hear of its fatal prevalence at Fort Harker, Kansas, among the United States soldiers, as well as among civilians in the neighboring villages, also in many other parts of the country. If we are not mistaken, it is destined to take a wider sweep the present season than the last. But it is consolatory to know that we are far better prepared to meet it, and successfully resist its progress. The pamphlet of Professor Bowling, of Nashville, contains some interesting facts, combined with some speculations; but we look in vain for any very accurate statistics in regard to the disease in any of the years mentioned. We are told that "from the 9th of June until the 1st of August, 1850, it is probable 500 persons perished in Nashville and its suburbs from cholera;" also, that "there could not have been less than 5000 cases, in a population of about 20,000, of which 500 proved fatal." No very reliable record, however, seems to have been kept, nor any minute and accurate observations made; not a single *post-mortem* is recorded. We cannot speak highly either of the treatment which is pronounced to have been the most successful, viz. "4 grs. opium, to five of calomel," *after each liquid evacuation.*" This treatment is declared to have succeeded, "except among fruit and vegetable eaters, where it produced "little or no effect." *Ice* eaten *ad libitum*, is stated to have best succeeded "in allaying thirst, gastric distress, and vomiting." In 1854, in May, June, and July, to the 11th inclusive, it is stated, there were 88 cases of interments from deaths of cholera in south Nashville and suburbs, including a population of about 30,000, "a large majority being among negroes and children." The drinking *water* was from wells, and contained much lime. In other parts of the city hydrant water was chiefly used. The generalizations of Prof. B. would seem to be rather surmises, or hypotheses, than conclusions legitimately drawn from well established facts. For example, in the way of food, he would forbid, "*every description of fruit, non-cereal vegetables, and animal products, as milk and eggs.*" *Bread* is allowed: also, good beef, mutton, chicken, ham, bacon, crackers, dry-toast, biscuit, plain corn-bread, tea and coffee. If persons living on such a diet, are attacked with cholera, "the system responds instantly to medicine," while it is said, the contrary is the case with the vegetable-eater. Crude, green, and stale vegetables are, no doubt, unhealthy food in places where cholera prevails, and so are fresh ripe fruits and vegetables, taken in excess; but there is no proof on record that goes to show that either of the latter taken in moderation will either excite an attack of cholera or necessarily insure a fatal result. In 1866, there seem to have been, as in former years, no very accurate records of cases of deaths from cholera, though Prof. B. estimates the latter at 1000 souls. "The cholera was twice as fatal here as in the great visitation of 1850." The daily number of deaths reached as high as 70. It is to be hoped, since the able Prof. Joseph Jones, M.D., is Health Officer of Nashville, we shall have correct mortuary tables of that city—as well as some other much needed municipal reforms. As 3000 dollars were expended for coffins for "cholera paupers," it is evident the mortality among that class must have been great. Two and a half per cent, only, of the population are stated to have died of the malady; no excessive mortality certainly. The large mortality on Blackwell's Island, 123 out of 800, is attributed by Dr. B. to the "free use of vegetables in a cholera atmosphere." "It is our deliberate opinion," says Prof. Bowling, "that if this rule is religiously observed" (abstinence from vegetables), "cholera, if it occur, is so shorn of its malignity, as to make it incapable of destroying life in the absence of doctors."

In 1833, 174 died of cholera in Nashville (so stated); in 1835, 66; in 1849, 311; in 1850, 316; in 1854, 88; in 1866, 800. "The Board of Health," it is said, "did all they could to bring fully before the people, the facts of the entire case!" But something more, we think, is necessary; not a word about the use of disinfectants, cleansing of streets, houses, lanes, alleys, etc.; only "hydrant water was given to any amount," and "medicines furnished gratis by certain first-class apothecaries!" The pamphlet closes with a very valuable letter from Prof. Jones from N. Y., giving the results of the experience of the "Metropolitan Board of Health" of N. Y., in regard to the use of disinfectants in checking the progress of the malady, and also as to the treatment.

II. The Report of the International Sanitary Conference which met at Constantinople in May, 1866, is already widely known to our readers, through abstracts already made in our pages. It has generally been acknowledged to be the most important and authoritative document on Asiatic cholera that has ever been published, and as such is worthy of the careful consideration of all municipal governments and members of the medical profession. It takes the most decided ground in favor of the doctrine of the communicability of cholera, of its progress from place to place solely by human agency, of the importance of restrictive measures to check free communication during cholera epidemics with infected districts, and of controlling the disease in its natural home. It is true, that many, who had closely studied the last irruption of Asiatic cholera into Europe from the East, and noticed how closely it followed the course of travel from that quarter, how its introduction into different places, before unaffected, was distinctly traceable to infection, by the importation of cholera patients, had become fully impressed with a belief of its infectious character, long before it made its appearance on board immigrant vessels in the port of New York in the fall of 1865. Hence the Metropolitan Board of New York, with wise and intelligent foresight, adopted measures to exclude the disease from the city by a rigid system of Quarantine, which, though successful for more than six months—during which the disease was confined to vessels in the lower bay—yet eventually proved of no avail, owing to the want of suitable places for detention and classification of emigrant passengers on land, and,

also, a relaxation of measures as regarded the introduction of persons into the city laboring under choleraic diarrhœa, through whom, there can be little doubt, the disease was propagated to places where it subsequently appeared. This most important fact has now been fully demonstrated; for the malady has been traced step by step, wherever it has appeared, and in every instance, it has been proved to have been conveyed through human intercourse. This was indeed sufficiently evident from facts in the history of former epidemics of cholera; but the old, obsolete, unphilosophical doctrines of *atmospheric contamination and epidemic constitution of the air* had taken such complete possession of the minds of the profession, that it was next to impossible to eradicate them. Even our teachers of medicine were so enslaved by these old hypotheses, that they were unwilling to admit the most obvious facts when placed before them. Their minds seemed not only befogged, but they clung to their delusions with a tenacity which nothing could weaken or destroy; and even now, instead of candidly admitting they were mistaken, and retracting what they had put forth on the subject, they continue to reiterate their exploded doctrines, though the whole medical world has rejected them.

Our limits will not permit any extended notice of this pamphlet of 108 pages, and we must, therefore, refer the reader to it as the most valuable document which has ever appeared on the subject. There is one question, however, discussed, which is so important as bearing on the question of quarantine, that it deserves special notice. It is this: "Are there conclusive facts which force us to admit that cholera can propagate itself to a distance by certain states of the atmosphere, by winds, or by any other similar change or modification of the surrounding mediums?"

As it has been abundantly demonstrated that epidemic cholera has never been developed spontaneously outside of India, it is unnecessary to discuss the question whether certain states of the soil, or certain hygienic conditions, can give rise to the disease (though they may favor its epidemic prevalence). The most important question connected with it is, whether it can be transported to a distance by a contaminated atmosphere; in other words, whether the cholera *virus* can be carried to a distance by winds, and thus be propagated? If so, then, quarantine restrictions must necessarily be of very questionable efficacy. The following quotation from the Report of the Convention shows their opinion regarding this point: "To prove that cholera may be propagated by the atmosphere beyond a certain distance, we need at least one conclusive fact; that is to say, one which establishes *the passage of the disease from an infected place to a healthy one without any possible previous communication.* Now this fact does not exist in science; and the Commission has been able to satisfy itself of the frivolousness of all the assertions which have been made of this kind." Again, "Undoubtedly, it has not always been possible to demonstrate the previous communication between an infected place and one subsequently infected; but wherever the inquiry has been made with care, and where the conditions of the locality admitted of a verification, this previous communication has been established." Again, "It is a law, up to the present time without exception, that cholera has never advanced more rapidly than man in his migrations."—(*p.* 40.)

There is another very important point, as the Commission state. An arrival of cholera at a port is a complex affair, comprehending man and all that directly belongs to him: his baggage, his effects, his merchandise, his animals, the ship which brings him, in fact everything which accompanies him; and, as cholera is transmissible by such means, a long voyage without any outbreak of the disease, or any appreciable symptoms, is no security against danger. *The present rule, therefore, that if emigrant vessels coming from places where cholera prevails, have had no cholera cases on board since they left an infected port, they are, therefore, to be regarded as safe, and the passengers with their effects landed, and go where they please, is an unsafe rule, and should be changed.* On the contrary, according to the Commission, the rule should be, to consider every such arrival as suspected, and place both ship and passengers under proper restrictions. We call the attention of Health officers particularly to this point.

In connexion with this pamphlet, it may be well to call attention to the conclusions of the "Cholera Conference" that recently met at the City of Weimar, in Germany, composed of the most distinguished sanitarians of Europe; we present this in the form of a synopsis, drawn up by the Registrar of the "Metropolitan Board of Health," Dr. Harris, as containing the latest and most authentic conclusions on the subject:

"*To the President Metropolitan Board of Health.*

"Dear Sir—Having been favored with an abstract of the discussions and concluding recommendations of the Cholera Conference that recently met at the city of Weimar, and having learned from Prof. Pettenkofer that the full stenographic report of the Conference will be published at Leipzic during the summer, I now lay before the Board of Health a synopsis of the discussions, and their conclusions as given in this abstract.

"You will recollect the polite invitation that was extended to New York to be represented at that important meeting. It turned out to be precisely such a Conference as the interests of public hygiene required, for the most practical and comprehensive questions were discussed by the leading sanitary scholars of Europe, nearly sixty delegates being present. The following conclusions were adopted, and I beg leave to present them here before giving the synopsis of the debates of the Conference.

"CONCLUSIONS AND RECOMMENDATIONS.

"I. The Conference expresses as its deliberate conviction that the efforts to arrest and prevent cholera by disinfectants should be continued in the most energetic manner.

"II. Disinfection will be entirely successful only where excremental matters are carefully gathered and kept from being cast about; when attention is given to cleanliness, and the means of health; and when the disinfection is performed by sanitary authorities in a compulsory manner.

"III. In places where the entire locality or district cannot be at once disinfected, it is advisable to disinfect throughout the places visited by the previous epidemics of cholera.

"IV. The general disinfection should be performed at the proper time, that is, before the epidemic is actually prevalent in town or place. Every house or spot that becomes infected, or is suspected to be so, must be kept constantly under the influence of disinfection.

"V. In regard to the best substances as disinfectants, though the testing of various articles is not yet completed, there have been found, to the present time, no more effectual substances than sulphate of iron (copperas) and the carbolic acid; and, as experience proves, we have no other disinfectants that can be employed with greater facility. A combination of both these disinfectants is therefore recommended.

"VI. The disinfection of clothing that has become

infected by cholera excrement is especially an important matter. For that purpose the Conference recommends that all such clothing be disinfected by boiling in water, or by chemical treatment in a proper solution of "zinc vitriol" (sulphate of chloride of zinc); and the Conference also recommends that special arrangements be made by which disinfection can be employed in all places, and at any hour, among or for the poor.

"VII. For the disinfection of sewers and drains, the Conference advises the trial of Mr. Sauvren's method. (The means used by Mr. Sauvren are not yet fully published, but they are believed to be similar to McDougall's—namely, a combination of carbolic or coal tar preparations, in a cheap form.)

"VIII. If cholera infects any house or spot, it is recommended that, if practicable, the house so situated in an infected place, or being infected, should be vacated, and the inhabitants should be removed from the infected spot.

"IX. It is especially recommended that the ground-water (that is, the water in the ground) about dwelling-houses, and all the grounds about habitations of every kind, should be preserved undefiled by any excremental matter of cholera; also, that all drinking water be undefiled and pure, and that where no pure water can be had, the water which must be used should be disinfected by boiling.

"Such were the final conclusions of the Conference in reference to the first duties of sanitary authorities and the people of any town that is threatened by cholera. The discussions were based upon the experience and studies of the distinguished gentlemen who had thus agreed to meet and compare their views, and the results of their observations. The attendants at the Conference were from various cities of Germany, Holland, Prussia, Austria, Hungary, and Russia. The history of cholera outbreaks among the troops in the war last year proved marvellously interesting, and conclusive on many points. Next in order of interest and importance was the history of infection by means of water contaminated by cholera excrement. Closely allied to the latter subject was the examination of evidence concerning the discoveries that have been made in regard to the particular means by which the cholera infection is transported and propagated. Lastly, and most practically useful, was the examination of evidences concerning the proper and best methods of disinfection, and the relations of such means to the control and promotion of cholera epidemics. The chief medical officer to the Privy Council of Great Britain presented the history of the outbreaks of cholera in London in connexion with the water of the East London Water Company, which, as Dr. Radcliffe has shown, was contaminated by cholera excrement. In the district where that water was used the epidemic burst forth as by explosion; while, subsequently, in other places it spread by the more usual methods, and in the more usual manner. Then, again, there were other instances where the epidemic spared all persons in certain asylums and hospitals who used privies that were entirely uncontaminated by cholera excrement, while the epidemic decimated the classes of inmates that used the latter. The Conference conceded that wells and reservoirs of drinking water were frequently contaminated by the cholera poison, by soakage into them of the infectious element from the cholera stools; but Profs. Pettenkofer, Wanderlich, Simon, and others, agreed that drinking water was not the most universally common means of communicating cholera to man. The influence of ground moisture, or more precisely of the ordinary ground-water, while such water or moisture is receding by drying of the ground after a wet period, was proved by such as daily used the same well water, but who used different privies, and frequented different and well separated yards, as we saw the same fact illustrated in two adjacent pavilions on Blackwell's Island last summer. The influence of different kinds of grounds in receiving and propagating the epidemic virus of cholera was examined, and Dr. Pfeiffer, of Vienna, showed the curious course which the epidemic pursued in passing through the great forest country of Thuringen last year; while the delegates from Dresden and some other places showed what conditions of the earth had permitted and favored the spread of cholera on their soil that covered certain granite rock districts. The outbreaks on Blackwell's Island and the rocky summit of Hudson City, fully bear out the conclusions of the Conference on the subject of cholera epidemics on rocky surfaces, and do not disprove the agency of the surface soil in propagating the virus when planted in such places. Examining the great mass of facts presented by the members of the Conference in regard to influence of the ground, and its retentiveness of undrained water, or being porous, and at times saturated and again undergoing a course of drying by evaporation, the more important conclusions seem to be as follows:

"1. That porous soils, and any kind of earth that retains and favors the ordinary kinds of fermenting filth, will readily retain and repropagate the virus of cholera when once the germinal virus has been introduced or planted by persons coming from infected places. That the mere altitude of a place is not the question that determines its susceptibility to cholera; that the moisture (ground-water), and the fluctuations of that moisture in a soil by rising and receding (drying), favors the propagation of cholera; that a sewer or drain may become the chief source of infection to some places where is no soil, or where the ground and everything except the sewers and drains have been disinfected.

"2. That Prof. Pettenkofer's use of the term ground-water should be understood, as he intended, to mean the standard of saturation by moisture in the soil, and that grounds which, upon their surface appear to be high and dry, may, nevertheless, be saturated with moisture; that is, have an excess of ground-water (or high ground-water); and that the sanitary drainage and drying which are necessary to protect a soil against repropagating the planted virus or germs of cholera must be deep and thorough. The history and topography of the cholera fields of Halle, Berlin, Zwickau, Thuringen, Helsingfors, and St. Petersburg, supplied admirable proofs of this great doctrine in sanitary drainage.

"3. Good proofs were adduced that there are some kinds of soil that seem to be natural disinfectants of cholera virus, and upon which an epidemic cannot spread except in filthy houses, sewers, &c. We have not time to make the abstract of the facts that will illustrate the true theory of this kind of exemption. We can say, however, that it is plainly important that regard should be given to the kinds of earth and materials used for filling up sunken lots, and that even the location of dwelling-places may sometimes be wisely a matter of choice as regards the nature of the soil.

"The facts concerning specific disinfection to destroy both the cholera virus and all susceptibility to material for its repropagation in a house or a district were well discussed in the Conference. The negative facts were specially important, for they showed that in a few places, as in the great prison at Halle, the epidemic swept forward regardless of the previous and continued disinfection of the grounds and nuisances with sulphate of iron. But in those instances it was proved that the sewers and drains were not disinfected, and that not

only were the infected spots particularly exposed to, and connected with such drains and sewers, but that the copperas solution had been relied upon without admixture with carbolic acid, and the powerful antiseptic agents which coal-tar contains. In Berlin there was great success in the use of permanganate of soda, with sulphuric acid added—that is, the success was achieved by the most rapid and powerful oxidization, in the same manner as we last summer disinfected the defiled clothing and bedding of the cholera sick by means of permanganate of potassa. The expensiveness of the method is the chief objection to it. Yet, for domestic and limited applications it is a perfect method for clothing and upholstery. The fact that with entire unanimity the Conference recommended that the main reliance for disinfection should be placed on the simpler and powerful agents—sulphate of iron and carbolic acid, which the Metropolitan Board unhesitatingly adopted at the beginning of the epidemic last year—will be ample warrant for our continuing to employ those cheap and effectual substances.

"The vital importance of perfect sanitary care of all persons sick or infected with cholera was illustrated in the history of the epidemic in every city. Disinfection alone, and especially the irregular and unsystematic, or unenforced applications of disinfection, did not always control the prevalence of cholera; indeed, such exclusive and unmethodical sanitary work often resulted in fatal disappointments. In some cities, as in Erfurth, even the carbolic acid was so freely used in some parts of the town in privies, that the wells in the vicinity of the privies flooded with that disinfectant, yielded water that tasted strongly of it; yet parts of Erfurth were neglected, and cholera was fearfully epidemic there. But it was conceded that in cities in which there was perfect, and systematic, and well-regulated sanitary disinfection combined with perfect care of the sick, and of all suspected persons, as was the case in the city of Bristol and some other favorite cholera haunts, the epidemic was controlled, and, by like faithfulness and skill, that it could and should be generally controlled in all civilized cities.

"Prof. Hirsch presented the argument and studies that favor the discovery of the precise nature of the poison that produces cholera, and the Conference commended and urged on the inquiries that have already, in the hands of Prof. Klob and Thome last year, resulted in discovering a minute microscopical growth that seems, thus far, to be exclusively produced in cholera excrements, and which obeys all the tests for the destruction as well as propagation of cholera. The spores of that little growth multiply with marvellous rapidity, and they are not destroyed by ordinary doses of chlorine, or chloride of lime, but are killed by sulphate of iron and carbolic acid.

"The Conference recommend that scientific naturalists, like the men who are now at work on these questions, should continue their researches. It was also recommended that observers of cholera should carefully study the conditions under which the epidemic is transported from place to place, and also study the relations of ground moisture (ground-water), and other local conditions that determine the boundaries of epidemic fields.

"It will be observed by these notes of a discussion that appears to have been conducted with the single object to find out what is known, that there was a clear knowledge of the practical wants of sanitary officers and governments. The nine propositions which the members of the Conference have submitted as their unanimous conclusions and recommendations I have placed at the beginning of this abstract, as being precisely the kind of information which a Board of Health most wishes to receive, and upon which it can base judicious practices. Fortunately for the good name of your Board as for the safety of the city last year, our practice was, from the first, based upon these doctrines, and the great minds that led in the Weimar Conference were the men that had most aided us in former years to deal with epidemic and infectious diseases. I am happy to learn that the Leipzig report is to be fully illustrated by maps and charts to show precisely what course cholera has pursued in European cities. We may hope to receive copies next month. I regret that the abstract forwarded by Prof. Pettenkofer cannot be entirely translated and placed in your hands to-day. These pages contain the gist of the whole, but the debates touched upon a great many other points. We are a little surprised that some conclusion and recommendation on quarantine was not reached. But, since the fact has been demonstrated that persons who travel away from an infected district may themselves, while yet journeying and not sick, spread cholera by means of excremental evacuations, it is not surprising that little reliance should be placed upon quarantine regulations as a means of preventing cholera from spreading in Europe.

"Respectfully yours,
"ELISHA HARRIS, Corresp. Sec. M. B. H."

III.—The circular from the War Department on cholera in the U. S. Army, drawn up by Assistant Surgeon J. J. Woodward, M.D., is a very able document, made up from official reports, with statistical tables exhibiting the monthly number of cases and deaths from cholera, and the allied bowel affections, for each post where the disease prevailed; and although the total number of cases is not very great, yet they bear a large proportion to the number of troops exposed to the disease; and the circumstances attending the transmission of the epidemic from post to post are so interesting, and so clearly demonstrative of the infectious nature of the disease, that it may be regarded as one of the most important documents on the subject yet published in our country.

The first case reported in the army, occurred at Fort Columbus, Governor's Island, New York Harbor, on July 3, 1866. The disease then prevailed in New York city. Recruits from Governor's Island carried cholera to Hart's Island, from thence it was carried by the troops to David's Island and Fort Schuyler; total number of cases among the troops in New York Harbor, 181, and 78 deaths. The steamship San Salvador, which left New York on the 14th of July, took on board 476 recruits from Governor's Island; on the second day out, cholera appeared on board, and she arrived at quarantine near Savannah, Georgia, with twenty-five sick with the disease, and three dead. The troops were landed at Tybee Island, where cholera prevailed during July and the first few days of August; altogether, 202 cases, and 116 deaths. Of ten white citizens residing on the island, nine were seized with cholera, and five died soon after the infected ship arrived. In the same manner recruits from Hart's Island carried the disease to New Orleans, and Galveston, Texas. In the former city, there were ninety-three cases among the white troops, and twenty-four deaths; and 254 cases and 149 deaths among the colored troops. Hence the disease was carried by detachments to the colored troops at Forts St. Philip's and Jackson, below New Orleans on the Mississippi river, where there were seventeen cases and eleven deaths. Afterwards the disease appeared among the troops at Ship Island, Miss., Baton Rouge, La., Shreveport, Brazos Santiago, Tex., White's Branch,

Tex., Brownsville, Indianola, San Antonio, Austin, Tex., Richmond, Va., Norfolk, Va., Carlisle Barracks, Pa., Jefferson Barracks, Me., Newport Barracks, Ky., Atlanta and Augusta, Ga., Louisville, Ky., Bowling Green, Ky., Nashville, Tenn., Memphis, Tenn., Vicksburg, and Fort Riley, Kansas, Fort Leavenworth, Ks., Helena and Little Rock, Ks., Huntersville and Fort Smith, Arkansas, Fort Gibson, Cherokee Nation, and a few other places.

It appears from the tables, that out of a total of 12,780 men, there were 2,908 cases of cholera reported, and 1,209 deaths; of these there were 1,749 cases and 706 deaths out of a mean strength of 9,083 white troops; and 950 cases and 501 deaths out of a mean strength of 3,697 colored troops. A few isolated cases made up a total of 2,724 cases and 1,217 deaths of cholera for the six months. Among the white troops, the number of cases of cholera reported during the six months, was 192.6, with 77.7 deaths per 1000 of strength. Of diarrhœa diseases, 741.8 cases and 7.5 deaths per 1000. For the colored troops, the number of cases of cholera reported, was 259.4, with 195.5 deaths per 1000 of strength; of diarrhœa diseases, 574.5 cases, and 3.5 deaths per 1000; of all other diseases, 833.9 cases, and 11.4 deaths per 1000.

In conclusion, Dr. Woodward remarks that "on the whole, it must be admitted that the general tenor of army experience during 1866, is strongly in favor of quarantine, and especially points to the danger to the army incurred by the distribution of recruits or other bodies of men from infected points."

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, MAY 24, 1867.

DR. H. B. SANDS, President, in the Chair.

UNUSUAL INJURY OF ELBOW-JOINT.

DR. BUCK exhibited a specimen of unusual injury of the elbow-joint. The specimen was taken from a cadaver, about fifty years of age, that was brought from the medical ward, and his attention was directed to the elbow. It was represented to have been fractured twenty years before. There was no history of the case obtainable. The limb, as it lay beside the body, presented a rather remarkably straight appearance, not having the slightest degree of abduction of the forearm upon the arm, but a little inclined to adduction, and in a position of rather extreme extension, so that there was some bulging forward at the elbow. After removing the specimen, and laying open the joint posteriorly, it was ascertained that the articular extremity of the humerus was entire, which was also the case with the head of the radius and the olecranon, but the coronoid process had evidently been separated by a fracture. There were two pieces that were fractured; the smaller, which occupied the outer side, was equivalent to a good-sized pea in volume; the other fragment was considerably larger. These two fragments were united to each other, and to the surfaces from which they had been separated, by fibrous tissue, and from the smaller fragment there were threadlike fibres crossing the joint, and terminating at the outer condyle of the humerus. There were two that were nearly parallel with each other, and were joined together after the manner of a nervous plexus.

In conclusion, Dr. Buck could not conceive of these bands being made up of inflammatory adhesions, but was inclined to coincide with the opinion of a friend, which was, that portions or strips of synovial membrane had been torn up at the time of the accident, and had eventually dwindled down to mere fibres. The specimen, however, was especially interesting in connexion with the extreme rarity of an uncomplicated fracture of the coronoid process.

DR. POST thought that the bands might be the result of adhesive inflammation, becoming much elongated during the course of the twenty years since the injury. He further remarked, that writers spoke of fractures of the coronoid process invariably attended with dislocation of the ulna backwards, a phenomenon constantly recurring. Dr. Buck's case, though an exception to this rule, admitted of an explanation in that there was not enough of the coronoid process knocked off to allow of the displacement.

DR. JACOBI remarked, that it would be worth while to decide as to whether the bands referred to were formed of false membrane or not, by an examination with the microscope.

RUPTURE OF SEMILUNAR VALVES: A QUESTION IN MEDICAL JURISPRUDENCE.

DR. FINNELL, on behalf of Dr. John Beach, exhibited a heart taken from a man fifty years of age. The deceased was of intemperate habits, and after a certain dinner was noticed sitting on his chair dozing, from which he slipped off, falling upon the floor. On his getting up some persons present remarked that he was intoxicated, which statement led to a quarrel, in which the man was pretty severely beaten about the face, breaking the bridge of his nose, and otherwise inflicting bodily injuries. The following morning he was found lying upon his face on the floor of his room, dead.

On post-mortem examination, at the instance of the coroner, there were no lesions found, except those about the heart. The disease of this organ was mainly confined to the aortic valves. The left ventricle was very much dilated, the three semilunar valves were much crippled by atheromatous deposits, and one of these latter valves showed a laceration which commenced at its free margin, and extended a few lines backwards towards the base.

The parties engaged in the quarrel being arrested on a charge of murder, it was of the utmost importance to determine whether the man died as the result of injuries received in the quarrel or not; in other words, was the rupture of the valve the cause of death? and if so, was the said rupture the direct result of the beating which the deceased is said to have received?

DR. KRACKOWIZER, assuming that the rupture was recent, did not think it could have been the cause of death, inasmuch as the rupture in itself was not a formidable one, and besides the little disturbance which it would excite in the circulation would hardly serve to make much impression of a serious nature upon an apparatus already crippled for a long time with serious heart lesions. It seemed to him that the man might well enough have died independent of any quarrel, from, for instance, paralysis of the heart from hyperextension of the ventricle.

A COLLECTION OF ANOMALIES IN A MONSTER.

DR. JACOBI presented the body of a new-born infant which, considering the number of existing anomalies, was in itself a collection of specimens. He remarked upon the subject as follows:

This infant was born at full term, and, as far as I know to the contrary, of healthy parents; the presentation was normal, no one save a midwife was present at the birth, and the deceased lived but half an hour. In the body of this child there are a large number of anomalies.

The malformations found are of three different types:

first, those which refer to arrest of development; second, those which refer to excess of development; and thirdly, the results of intra-uterine disease.

We will commence with the head. The right eye is perfectly normal, but the left is evidently much atrophied, and contains in its centre a yellowish-grey looking point which is in all probability the crystalline lens. The exact description of the anomalies present has been furnished me by Dr. Althof.

Orbit, normal; fossa glandulæ lachrymalis, very deep; lids, lachrymal apparatus, and muscles well developed; also the nerves; vessels could not be traced.

Eyeball: longitudinal axis, 9 mm.; vertical axis, 6 mm.; horizontal axis, 7 mm.

Cornea: Diameter, 2½ mm. Epithelial cover changed into a compact mass—its cells could not be separated into the usual different layers. Bowman's membrane only fragmentary near the periphery. The proper tissue of the cornea had lost its characteristics—none of its normal constituents to be clearly distinguished. Descemet's membrane very well conserved—its cells in a state of proliferation. *Iris:* very much thickened—cellular tissue well conserved—no trace of either elastic fibres or Zinn's membrane—the whole enveloped in a very massive coat of organized lymph—firmly adherent to the lens. *Ciliary processes:* have disappeared—covered by lymph. *Lens:* dimensions normal—capsular (pyramidal) cataract—cells of anterior capsule partly conserved—lens fibres opaque, broken and split, full of molecular deposit—fatty degeneration in some parts near the posterior pole—altogether enveloped in a thick layer of organized lymph—no trace of zonula. *Corpus vitreum:* a tough, shrunken mass, without any organization. *Choroidea:* fully developed in all its layers—contains pus in great quantities—very numerous so-called "ganglion-cells"—exudations on glass-membrane (first time they came under my observation in so young an eye). *Retina:* entirely detached—rods and cones, also outer granules totally destroyed—traces of layer of inner granules—very fine ganglion-cells (perfectly normal)—varicose nerve-fibres with numerous nuclei. *Optic nerve:* well developed—papilla much swollen—central artery larger than usual—lamina cribrosa to be demonstrated without any difficulty—entrance of nerve normal.

This state of things proves that we have not to deal with a malformation of the eye, but with an intra-uterine irido-choroiditis.

The principal thing besides to be exhibited in the head is the presence of double hare-lip and cleft palate. The soft palate is easily distinguished on the two sides, the fissure being in the median line. The intermaxillary bone is separated by a large gap from the alveolar processes of the maxillary bone on each side, and is somewhat smaller than normal, rounded on its two sides, but especially so on the left, so that the second incisor tooth is protruding through the alveolar process. As in all these cases, the integuments are more retracted than the intermaxillary bone itself. The vomer is normal, but as usual bent a little to one side.

Another arrest of development is in the shape of a fissure in the abdominal integuments, in the neighborhood of the umbilicus, constituting umbilical hernia. There is found at the insertion of the umbilical cord, and hanging to the right of the median line, a tumor of the diameter of an inch or an inch and a quarter; this tumor evidently consists of nothing else but the amniotic covering of the umbilical cord, through which, in the fresh state of the parts, intestine could plainly be seen. There is another fissure in the left side of the diaphragm, constituting what has been called a diaphragmatic hernia, through which protrudes a greater portion of the spleen, as well as the stomach, covered, however, with the diaphragmatic pleura. This hernia then is not complete, as far as the viscera of the abdomen are concerned. There is still another fissure, to which I will return presently.

I will next show the supernumerary limbs. There are two sixth toes, both adjoining the fifth, both tolerably well developed, both having two phalanges, and both showing nails. This one on the left foot is connected with the second phalanx of the fifth toe, but the other one on the right side is connected by means of a joint, both to the metatarsal bone and the first phalanx of the fifth toe. The supernumerary fingers are simple appendages joined to the fifth finger of each hand, by integumentary tissue.

In regard to the umbilical hernia there was one point to which my attention was directed. I thought that inasmuch as this hernia was developed very early in fœtal life (the fifth or sixth week of utero-gestation), the development of the intestinal canal was somewhat impeded. On examination, however, I was struck with the rather normal appearance of the intestines. I thought that the intestines might be shorter than normal, but now I find that the colon of this infant is at least as long as we ordinarily find it in the fœtus. Generally it is very long in the new-born, so much so, that especially in the pelvic region the sigmoid flexure is not found on the left side but on the right; that there are, as a rule, sometimes two, and not unfrequently, as in this instance, three sigmoid flexures.

A very important anomaly belonging to the same class will be found in the heart. In the first place, contrary to the rule, the left side of the heart is more developed than the right; secondly, the aorta, instead of being small between the heart and the ductus arteriosus, was unusually large; and thirdly, the ductus arteriosus was very small indeed, notwithstanding the pulmonary artery was of normal size. Searching for a clue to these phenomena, I find the inter-ventricular septum open; and further, the entrances into the aorta and pulmonary artery are side by side, and originate in the same ventricle. Thus this is an instance of the common origin of the pulmonary artery and aorta in the left ventricle. I have not been able to look up more than one case of the kind on record. The possibility of a child living or developing to this extent is simply explained by the fact that the two ventricles in this case have acted as one, just as if there were present no septum at all.

There are a few other anomalies; for instance, the vertebral artery, instead of originating in the subclavian, takes its rise from the aorta itself, which I believe is not so very uncommon. The venæ cavæ are large, but normal in every respect.

[To be continued.]

NEW YORK ACADEMY OF MEDICINE.

STATED MEETING, JULY 5, 1867.

DR. ALFRED C. POST, PRESIDENT, in the Chair.

THE ECONOMY OF HUMAN LIFE.

DR. A. N. BELL read a paper entitled as above, in which he reviewed the various methods adopted by the ancients and moderns to secure the registration of statistical facts bearing upon the duration of human life. He alluded to the attempts made by Severus, Verranus, and Aurelius, which seemed to prove that the average life of the Roman citizen was 30 years. The city of Geneva, Switzerland, had some valuable mortuary tables, which with some intermissions dated back to 1549. Sweden and England also quite early turned

their attention to the same subject—in the latter country the Carlisle tables, which were wrong in principle and not to be depended upon, although generally adopted by Life Insurance Companies, originated.

He then briefly adverted to the causes tending to abreviate life, and maintained that proper food was much more important than good air and the most salubrious surroundings.

Dr. Griscom commented upon certain portions of the paper, and alluded to the fact that the 21st ward contained Bellevue Hospital. This, he thought, was a fact which did not belong to the ward, and should be eliminated in the statistical computations.

Dr. Bell said that the authorities were given in the foot-notes of his paper, and that some of them were derived from the reports of the late City Inspectors.

Dr. Griscom maintained that the statistics of the late City Inspectors were not to be relied on.

Dr. Harris thought that Dr. Bell had treated his subject with a great deal of candor, and had carefully discriminated between the practical and irrelevant. He moved that the thanks of the Academy be presented to Dr. Bell, which was unanimously carried.

In reply to certain inquiries, he stated that the records of other cities did not include the period of illness, which he regarded as of great practical value. The exactness of diagnosis in final causes of death he considered very important.

THE POWERS OF THE HEALTH BOARD AND THE PREROGATIVES OF CORONERS.

Dr. Rogers alluded to a case where "a certificate of death" had been given in a case not seen for three months one of the coroners at the request of a physician more conversant with the case and who desired an autopsy to demonstrate the diagnosis, suspended the funeral services for only a short time. He wished to know whether the physician in such cases would be sustained by the Health Board.

Dr. Harris thought it the duty of the physician to procure an autopsy when there was a doubt regarding the cause of death; and said that there was no law to prevent it. The case may then be surrendered to the coroners.

Dr O'Sullivan inquired what was to be done in those moribund cases seen only once, to which physicians of the poorer districts were summoned, evidently and mainly with the view to secure a certificate without the intervention of the coroner.

Dr. Harris regarded it inconsistent to refuse. The proper plan would be, if a post-mortem were refused, to give the cause of death as simply "unknown," and supplement it afterwards if possible.

Dr. Vankleek desired to know if the coroner was a judicial officer, and if when he was satisfied that there was no occasion for an inquest the physician could demand an inquest in the interest of vital statistics merely.

Dr. Harris replied that it was the coroner's office to take cognizance of all cases of violent or sudden deaths. He substantially recited the law on the subject.

[The question was then debated at some length, but without arriving at any express conclusion.]

Dr. Downs raised the point whether or not as a matter of courtesy the attending physician should not be invited by the coroner to be present at the inquest.

Dr. Harris thought that the attending physician should be invited.

DELEGATES TO THE INTERNATIONAL MEDICAL CONGRESS OF PARIS.

Drs. John C. Dalton, Fordyce Barker, and Charles D. Smith were unanimously elected delegates from the Academy for the International Medical Congress at Paris.

RESULT OF AN OPERATION FOR CARIES OF THE OS CALCIS.

Dr. Burrall presented to the Academy the patient upon whom he had operated and whose case had been published in the Medical Record (vol. ii., p. 171). The success of the operation was complete.

The Academy then adjourned.

Stated Meeting, June 19, 1867.

Dr. Alfred C. Post, President, in the Chair.

INSANITY.

Dr. D. Tilden Brown read the paper with the above caption from the pen of Dr. Butler of Providence, R.I. a synopsis of which appeared in the Medical Record (vol. ii., p. 125), as part of the Proceedings of the American Medical Association.

MR. HOFF AND THE ACADEMY.

Dr. Anderson presented a preamble and resolutions already published condemnatory of Mr. Hoff for adroitly using the name of the Academy in seeming endorsement of his nostrum.

The Academy then adjourned.

Called Meeting, July 8, 1867.

Dr. Alfred C. Post, President, in the Chair.

MEDICAL ELECTRICITY.

Dr. G. M. Beard read an interesting paper upon this subject, after which the Academy adjourned.

Correspondence.

DR. HERZOG ON CHOLERA—LETTER FROM DR. BURRALL.

To the Editor of the Medical Record.

Sir—The following sentence in Dr. Herzog's communication to the Record of July 1st requires a slight explanation, lest the quotation made in the little work to which he has referred should be thought to unqualifiedly endorse Drasche's views. Dr. Herzog writes:

"I must further mention that the objection made to the whole doctrine of this second point* by Drasche, and quoted in Prof. Clark's lectures and Dr. Burrall's book, has been already fully contradicted, 1861, as unfounded on facts."

In the book referred to, after a notice of Drasche's views, as well as those of Dr. Lorange and Dr. W. H. Thomson on epidemics of cholera in Beyroot, the following conclusions were arrived at—conclusions which have, I think, not been weakened by the teachings of the late epidemic:

"Such facts seem to show that a cholera epidemic may prevail upon a dry and rocky stratum, in which the moisture lies more than fifty feet below the surface, when it appears among a people careless of the ordinary laws of health, and in the vicinity of an abundance of decaying excretions; also that such excretions favor the spread of cholera more than a malarious atmosphere. At the same time, the fact that the disease was not

* The dependence of cholera epidemics upon subsoil waters as one essential point.

indefinitely protracted does not weaken the theory that the dejections contain the infectious material, for the striking mortality among the scavengers in Beyroot is an additional argument to the many more in its favor; it only proves that the laws upon which the duration of a cholera epidemic depend are still unknown."

Respectfully, F A. BURRALL, M.D.

THE UTERINE ELEMENT IN PRACTICE AGAIN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—In this article I will touch on some points that I had not space for in my previous one.

Many specialists talk of ulceration of the *os uteri* as if it were a very common thing. Now in my experience, which has by no means been a small one, it is very uncommon. And this is the experience of many esteemed friends in our profession. The lesion which I have most often found does not at all deserve the name of ulceration. It is a small patch of redness, sometimes wholly on a level with the rest of the surface, and sometimes a little raised, and occasionally presenting something of a fungoid appearance, but never depressed. Commonly touching this a few times with nitrate of silver suffices to remove it. And I have no doubt that this lesion is often removed without any local application, by the use of remedies addressed solely to the state of the general system, just as is true of many other local difficulties; not so quickly, however, as when the local application is used also.

Dr. Meigs, who has had a similar and of course a much larger experience than mine, on this point, I find on referring to his article on diseases of the neck of the uterus in the sixth volume of the Transactions of the American Medical Association, speaks of the folly of calling such lesions ulcers, and says emphatically that "an ulceration of the womb is among the rarest of diseases."

It is astonishing what eyes some of these specialists have. Their declarations often bring to my mind the old couplet,

> "Optics sharp, it needs I ween,
> To see what is not to be seen."

In one of the last cases in which I witnessed the lesion above referred to, a physician had given—yes, given—the patient womb on the brain by telling her that she had a very large ulcer. I found nothing but one of these red patches—quite a small one—which was cured by some three or four applications of nitrate of silver. It was far from curing the patient, however, for it did not reach the chief source of the difficulty, the brain.

And here I must notice one practice which merits no milder term than abominable, but which I fear is somewhat common. I have said that some of the specialists on female diseases are very instructive and communicative with their patients and their friends. They take special pains to make them understand the nature of their complaints. In doing this some have gone so far as to let friends of their patients look into the speculum and see for themselves the ulcers, which was, of course, a very intelligent and satisfactory act. Perhaps, in the march of modern improvement, they will soon get so far as to let the patients themselves look in, by means of reflectors adjusted for the purpose.

In the case I have just referred to, this looking in was practised, as I learned, in this way: On examining the patient I found that a lady-friend of hers was standing by me, trying to look into the speculum, and as I seemed rather surprised, she informed me that Dr. —— asked her to look in and see the awful ulcer that was there. I have already said that there was nothing there but a small red patch, and yet Dr. —— only a few days before saw a large ulcer. What the lady saw, thinking it to be an ulcer, I know not—I did not care to discuss matters of diagnosis with her, though Dr. —— might have done so.

Here is another case. A physician of homely good sense, who never has used a speculum, but who knows more about female diseases than some who make a very common use of it, was consulted by a man in regard to a difficulty affecting both himself and his wife, and was told plainly that he had contracted gonorrhœa, and had given it to his wife, and the doctor prescribed for both accordingly. Soon after, being called in to the family for some purpose, the wife said to him, "I have had Dr. —— to see me, and he has examined me with an instrument, and he found an ulcer on the mouth of the womb." "Poh!" said he. "Well, it's true," said she, "for the doctor told Mrs. —— to look in, and she saw it."

I give still another case. A friend whom I happened to meet, consulted me incidentally in regard to his wife's case, stating that she had for some time been in ill-health; that she had recently, though very reluctantly, come under the care of one who had made a specialty of female diseases, and that he had found an ulcer on the mouth of the womb. I doubted very much the truth of the diagnosis, simply because he said further that he had seen the ulcer himself, and was quite disposed to talk about its appearance. I was so disgusted that I had very little to say in regard to the case—disgusted not with the husband, but with the physician, who had probably egregiously imposed upon a non-medical man, and had certainly transgressed the plainest rules of delicacy in thus indoctrinating him so unnecessarily, and probably fruitlessly, on such a subject and in such a manner.

Perhaps your readers will say that physicians who do such things cannot be respectable men. But really all the three that I have alluded to, have a respectable standing in the profession, and one of them is a very prominent man, known widely, and particularly as a specialist in female diseases.

If these and kindred practices are allowed to extend themselves, we may soon have ulcers and displacements of the womb talked about in promiscuous circles as freely as we now do fever, or colic, or cholera. I have sometimes felt a little queer when young ladies have had something to say in the presence of gentlemen about cases of dysentery and diarrhœa, and I am very much afraid that some of them will make me feel still more queer by remarking on the suffering of some of their friends from diseases of the womb. The tendency certainly is towards such offences against propriety and true delicacy.

There are some other points still that I must defer to another article.

MEDICAL REGISTER OF THE CITY OF N. Y. FOR 1867. JOHN SHRADY, M. D., Editor. N. Y. PRINTING Co., 81, 83, 85 Centre St.

Medical Items and News.

PERSONAL.—"DR. MARY E. WALKER, according to a Paris correspondent (July 8), was present at the Fourth of July banquet at the Grand Hotel, where she was wrapped up, *à la* Kirby, in the American flag. She evidently wanted to make a speech, but would not be heard. She wears her medal, voted her by the American Congress for brave womanly cares and attentions bestowed upon sick and wounded soldiers on the field and in the hospitals during the war, and for four months' martyrdom in the Libby prison. This medal has procured the 'doctor' admission into the medical circles here, and given her, I am informed, great facilities for observation."

SURGEON J. H. BAXTER, United States Volunteers, late chief medical officer Provost Marshal General's Bureau, was confirmed by the Senate as Medical Purveyor, United States Army, with the rank of Lieutenant-Colonel. This promotion in no way interferes with the completion of the medical report of the Provost Marshal General's Bureau, upon which, in accordance with an Act of Congress, Dr. Baxter is now engaged.

BREVET-LIEUT.-COLONEL J. R. SMITH, Surgeon United States Army, has been relieved from duty as Medical Director of the Fourth Military District, and assigned to duty as Post Surgeon at Jefferson Barracks, Missouri, relieving Brevet-Colonel E. Smith, Surgeon United States Army, who has been assigned to duty as Medical Director of the Fourth Military District.

DR. WM. T. NEALIS has been appointed Physician to the City Prison by the Commissioners of Public Charities and Correction.

DR. ELLSWORTH ELIOT has been elected one of the Trustees of the College of Physicians and Surgeons, *vice* Dr. Benj. Ogden, deceased.

JAMES R. WOOD, M.D.—We take pleasure in announcing that the degree of LL.D. has lately been conferred upon Dr. Wood by the Genesee College.

DR. CHARLES E. MORGAN, of this city, died suddenly August 4. We will give an obituary notice of the deceased in our next.

NEW YORK HOSPITAL.—Dr. James W. McLane has been elected one of the attending physicians to the New York Hospital, vice Dr. Thomas B. Dash, resigned.

SENECA CO. MEDICAL SOCIETY. — The anniversary meeting of the Seneca County Medical Society was held at the Eagle Hotel, in Waterloo, on Wednesday, July 10th. The President of the Society, Prof. Bolter, of Ovid, delivered an interesting address. The election of officers for the ensuing year resulted as follows:—*President*, Dr. O. S. Patterson, Waterloo; *Vice-President*, James Flood, Lodi; *Secretary*, S. R. Welles, Waterloo; *Treasurer*, E. J. Schoonmaker, Tyre; *Censors*, W. W. Wheeler, Farmer Village; A. Emens, Fayette; J. Dunn, Lodi.
